We’ll use as an illustration a synthesis of a rare sugar, methyl mycaminoside, containing five chiral centres. Only one chiral centre comes directly from the chiral pool—the rest are introduced diastereoselectively. The naturally derived, enantiomerically pure compound used as the starting material is (S)-lactic acid. The starting chiral centre, preserved right through the sequence, is ringed in green.

The ring was built up using familiar chemistry from acetylated (S)-lactic acid, and a cyclization step introduced the second chiral centre in the final step of the scheme below. The methyl group goes pseudoequatorial on the newly formed ring, while the anomeric effect, which was explained on p. 801 of Chapter 31, induces the methoxy group to prefer the pseudoaxial position.

The third stereogenic centre was controlled by reduction of the ketone from the axial direction to give the equatorial alcohol, which then directed introduction of the fourth and fifth stereogenic centres by epoxidation.
Finally, the simple nucleophilic amine Me₂NH attacks the epoxide with inversion of configuration to give methyl mycaminoside. The conformational drawing shows that all substituents except the MeO group, which prefers to be axial because of the anomeric effect. Starting from an enantiomerically pure compound containing one chiral centre, four new chiral centres are introduced in sequence by diastereoselective reactions of various kinds. The final product is necessarily a single enantiomer.

The structure and synthesis of penaresidin

Our last example is a natural product called penaresidin A. It was isolated from a Japanese sponge in 1991, and is now known to have the structure shown below. When it was first discovered, it proved difficult to find out the stereochemistry and, in particular, the relative stereochemistry between the two remotely related groups of chiral centres was not initially known.

What is sure is the relative stereochemistry around the four-membered azetidine ring: the NMR methods described in Chapter 31 give that. What is also certain is that natural penaresidin A is enantiomerically pure. What Mori and his co-workers set out to do was to make, using unambiguous stereoselective methods, the possible diastereoisomers of penaresidin A to discover which was the same as the natural product.

The challenge of constructing the three chiral centres at the left-hand end of the molecule can be solved by taking just one of them from a natural source—in this case the amino acid L-serine. The amino group of serine was protected as the Boc derivative, and the hydroxyl and amino groups condensed with the dimethoxyacetal of acetone to form a five-membered ring. Now the free ester could be reduced with LiBH₄ and oxidized to the aldehyde by the Swern method (Chapter 27).

How will this aldehyde react with nucleophiles such as lithiated alkynes? Consider a Felkin–Anh transition state: again, we know that the substituted nitrogen atom, being electronegative and bulky, will lie perpendicular to the carbonyl group in the most reactive conformation. Looking at the two alternatives shown below, it’s easy to see that the one on the right allows unhindered attack, and in the synthesis an alkynyl anion was used to make the product shown.
The alkyne was then reduced to an E alkene by a dissolving metal reduction, a step which also hydrolysed the five-membered heterocycle. The next step, an epoxidation, is needed to install the third of the chiral centres at the left-hand end of penarisidine. However, hydrogen-bond directed epoxidation of this allylic alcohol would be expected to give the syn product shown, which has the wrong relative stereochemistry between the brown OH group and the epoxide.

The solution is to use a large blocking group to prevent this brown OH group hydrogen bonding to the m-CPBA. The t-butyldimethylsilyl group (TBDMS) is the best, and when both OH groups are protected, some of the right diastereoisomer is formed by attack of m-CPBA on the top face of the alkene. Reduction of the epoxide with DIBAL (i-Bu2AlH) now gives the correct diastereoisomer.

To close the ring, the green hydroxyl group was converted to a good leaving group, mesylate (MeSO3−), ready for an attack by the nitrogen with inversion on treatment with base. Make sure you can see how inversion at this centre gives the stereochemistry shown! The chemists knew at this stage they were on the right track with regard to relative stereochemistry because the NMR spectrum of structures containing any long alkyl chain R were very similar to that of the natural compound.

**Confirming the stereochemistry by synthesis**

The other two chiral centres at the right-hand end of the chain are so far removed from the ring (by 10 CH2 groups) that there is no simple way to determine their stereochemistry relative to the three at the left-hand end by NMR. The solution to problems of assignment like this is often to make the various isomers by unambiguous synthesis and compare the NMR spectra of the natural and synthetic compounds. This is what Mori did in this case.

The chiral pool can again be called into play by using another amino acid, l-isoleucine, as starting material. First the amino group must be converted to a leaving group by diazotization with nitrous acid (sodium nitrite in dilute HCl) and substituted by water to give a hydroxy acid. The acid is esterified and reduced to a diol.
Conversion of the diol's primary hydroxyl group to a leaving group (here a tosylate) allows the epoxide to be formed with retention of the two stereogenic centres of the starting material. Cyclization in base gives an epoxide. Overall, the enantiomerically pure starting material is converted stereospecifically into a single enantiomer of a single diastereoisomer of the epoxide.

Before we go on, look back at the first reaction of this sequence—the conversion of L-leucine to the hydroxy acid. The stereochemistry may surprise you: look carefully and you will see that the amino group has been displaced with retention of stereochemistry. Retentive substitutions usually indicate double inversions, and here the carboxylic acid gets involved in the displacement to give (with inversion) a very unstable compound called an $\alpha$-lactone whose strained ring is opened by water, also with inversion.

The epoxide may now be opened with a nucleophile to give the right-hand half of the target molecule. The alkyne shown below, which has an anti relationship between the hydroxyl and methyl groups, was made and linked to the left-hand half of penaresidin A by using it to attack the aldehyde the method described above. However, the final product was not the same as natural penaresidin A!

Clearly, some aspect of relative stereochemistry was wrong. So the synthesis was repeated, this time using the syn diastereoisomer of the substituted alkyne obtained using one of the methods we will describe in Chapter 41. With this isomer the final compound had spectroscopic data identical with the natural product, and the question of its stereochemistry was solved. It is not uncommon for synthesis to be the only reliable way of proving the detailed structure of a compound.
Looking forward

Once you have got hold of a molecule as a single enantiomer, however simple that molecule may be, you can always use reliably diastereoselective reactions of the type described in this chapter and the one before to decorate it with further chiral centres. This is a very important point that underlies the field of asymmetric synthesis, which we will cover in Chapter 41. There you will see developments of the ideas we have just been describing, where chiral centres derived from nature are used to introduce new stereochemistry even though they themselves need not appear in the final product. But before we move on to such reactions, we need to cover a handful of important new reaction mechanisms, many of which provide further ways of introducing new stereochemical features into molecules. The first of these new classes of reactions is cycloadditions.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
Pericyclic reactions 1: cycloadditions

A new sort of reaction

Most organic reactions are ionic. Electrons move from an electron-rich atom towards an electron-poor atom: anions or cations are intermediates. Formation of a cyclic ester (a lactone) is an example. The reaction involves five steps and four intermediates. The reaction is acid-catalysed and each intermediate is a cation. Electrons flow in one direction in each step—towards the positive charge. This is an ionic reaction.

![Chemical structures](image)

This chapter is about a totally different reaction type. Electrons move round a circle and there are no positive or negative charges on any intermediates—indeed, there are no inter-
mediates at all. This type of reaction is called **pericyclic**. The most famous example is the **Diels–Alder reaction**. This reaction goes in a single step simply on heating. We can draw the mechanism with the electrons going round a six-membered ring.

\[
\begin{array}{c}
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{+} \\
\text{heat} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\text{O} \\
\end{array}
\]

Each arrow leads directly to the next, and the last arrow connects to the first. We have drawn the electrons rotating clockwise, but it would make no difference at all if we drew the electrons rotating anticlockwise.

Both mechanisms are equally correct. The electrons do not really rotate at all. In reality two \(\pi\) bonds disappear and two \(\sigma\) bonds take their place by the electrons moving smoothly out of the \(\pi\) orbitals into the \(\sigma\) orbitals. Such a reaction is called a **cycloaddition**. We must spend some time working out how this could happen. First, just consider the orbitals that overlap to form the new bonds. Providing the reagents approach in the right way, nothing could be simpler.

The black \(p\) orbitals are perfectly aligned to make a new \(\sigma\) bond, as are the two green orbitals, while the two brown orbitals are exactly right for the new \(\pi\) bond at the back of the ring. As this is a one-step reaction there are no intermediates but there is one transition state looking something like this:

\[
\text{transition state has six delocalized } \pi \text{ electrons}
\]

One reason that the Diels–Alder reaction goes so well is that the transition state has six delocalized \(\pi\) electrons and thus is aromatic in character, having some of the special stabilization of benzene. You could look at it as a benzene ring having all its \(\pi\) bonds but missing two \(\sigma\) bonds. This simple picture is fine as far as it goes, but it is incomplete. We shall return to a more detailed orbital analysis when we have described the reaction in more detail.
General description of the Diels–Alder reaction

Diels–Alder reactions occur between a conjugated diene and an alkene, usually called the dienophile. Here are some examples: first an open-chain diene with a simple unsaturated aldehyde as the dienophile.

\[
\text{diene} \quad \text{dienophile} \quad \rightarrow \quad \text{product}
\]

The mechanism is the same and a new six-membered ring is formed having one double bond. Now a reaction between a cyclic diene and a nitroalkene.

\[
\text{diene} \quad \text{dienophile} \quad \rightarrow \quad \text{product}
\]

The mechanism leads clearly to the first drawing of the product but this is a cage structure and the second drawing is better. The new six-membered ring is outlined in black in both diagrams. A more elaborate example shows that quite complex molecules can be quickly assembled with this wonderful reaction.

The diene

The diene component in the Diels–Alder reaction can be open-chain or cyclic and it can have many different kinds of substituents. There is only one limitation: it must be able to take up the conformation shown in the mechanism. Butadiene normally prefers the s-trans conformation with the two double bonds as far away from each other as possible for steric reasons. The barrier to rotation about the central \( \sigma \) bond is small (about 30 kJ mol\(^{-1}\) at room temperature) and rotation to the less favourable but reactive s-cis conformation is rapid.

The ‘s’ in the terms ‘s-cis’ and ‘s-trans’ refers to a \( \sigma \) bond and indicates that these are conformations about a single bond and not configurations about a double bond.
Cyclic dienes that are permanently in the s-cis conformation are exceptionally good at Diels–Alder reactions—cyclopentadiene is a classic example—but cyclic dienes that are permanently in the s-trans conformation and cannot adopt the s-cis conformation will not do the Diels–Alder reaction at all. The two ends of these dienes cannot get close enough to react with an alkene and, in any case, the product would have an impossible trans double bond in the new six-membered ring. (In the Diels–Alder reaction, the old σ bond in the centre of the diene becomes a π bond in the product and the conformation of that σ bond becomes the configuration of the new π bond in the product.)

The diene

The diene must have the s-cis conformation.

The dienophile

The dienophiles you have seen in action so far all have one thing in common. They have an electron-drawing group conjugated to the alkene. This is a common, although not exclusive, feature of Diels–Alder dienophiles. There must be some extra conjugation—at least a phenyl group or a chlorine atom—or the cycloaddition does not occur. You will often see the reaction between butadiene and a simple alkene (even ethylene) given in books as the basic Diels–Alder reaction. This occurs in only poor yield. Attempts to combine even such a reactive diene as cyclopentadiene with a simple alkene lead instead to the dimerization of the diene. One molecule acts as the diene and the other as the dienophile to give the cage structure shown.

Cyclopentadiene

Cyclopentadiene is formed in considerable amounts during the refining of petroleum. It exists as its dimer at room temperature but can be dissociated into the monomer on heating—the effect of the increased importance of entropy at higher temperatures (Chapter 12). It can be chlorinated to give hexachlorocyclopentadiene, and the Diels–Alder product of this diene with maleic anhydride is a flame retardant.

Simple alkenes that do undergo the Diels–Alder reaction include conjugated carbonyl compounds, nitro compounds, nitriles, sulfones, aryl alkenes, vinyl ethers and esters, haloalk-
enes, and dienes. In addition to those you have seen so far, a few examples are shown in the margin. In the last example it is the isolated double bond in the right-hand ring that accepts the diene. Conjugation with the left-hand ring activates this alkene. But what exactly do we mean by ‘activate’ in this sense? We shall return to that question in a minute.

Dieldrin and Aldrin

In the 1950s two very effective pesticides were launched and their names were ‘Dieldrin’ and ‘Aldrin’. As you may guess they were made by the Diels–Alder reaction. Aldrin is derived from two consecutive Diels–Alder reactions. In the first, cyclopentadiene reacts with acetylene to give a simple symmetrical cage molecule ‘norbornadiene’ (bicyclo[2.2.1]heptadiene). Norbornadiene is not conjugated and cannot take part in a Diels–Alder reaction as a diene. However, it is quite strained because of the cage and it reacts as a dienophile with perchlorocyclopentadiene to give Aldrin.

![Diagram of norbornadiene and Aldrin](image)

This is quite a complex product but we hope you can see how it is made up by looking at the two new bonds marked in black. Dieldrin is the epoxide of Aldrin. The use of these compounds, like that of many organochlorine compounds, was eventually banned when it was found that chlorine residues were accumulating in the fat of animals high up in the food chain, such as birds of prey and humans.

The product

Recognizing a Diels–Alder product is straightforward. Look for the six-membered ring, the double bond inside the ring, and the conjugating group outside the ring and on the opposite side of the ring from the alkene. These three features mean that the compound is a possible Diels–Alder product.

The simplest way to find the starting materials is to carry out a disconnection that is closer to a real reaction than most. Just draw the reverse Diels–Alder reaction. To do this, draw three arrows going round the cyclohexene ring, starting the first arrow in the middle of the double bond. It doesn’t, of course, matter which way round you go.

![Diagram of disconnection](image)

The reaction couldn’t be simpler—just heat the components together without solvent or catalyst. Temperatures of around 100–150°C are often needed and this may mean using a sealed tube if the reagents are volatile, as here.

![Reaction diagram](image)

Stereochemistry

The Diels–Alder reaction is stereospecific. If there is stereochemistry in the dienophile, then it is faithfully reproduced in the product. Thus cis and trans dienophiles give different diastereoisomers of the product. Esters of maleic and fumaric acids provide a simple example.
In both cases the ester groups simply stay where they are. They are cis in the dienophile in the first reaction and remain cis in the product. They are trans in the dienophile in the second reaction and remain trans in the product. The second example may look less convincing—may we remind you that the diene actually comes down on top of the dienophile like this:

One of the CO₂Me groups is tucked under the diene in the transition state and then, when the product molecule is flattened out in the last drawing, that CO₂Me group appears underneath the ring. The brown hydrogen atom remains cis to the other CO₂Me group.

The search by the Parke-Davis company for drugs to treat strokes provided an interesting application of dienophile stereochemistry. The kinds of compound they wanted were tricyclic amines. They don’t look like Diels–Alder products at all. But if we insert a double bond in the right place in the six-membered ring, Diels–Alder (D–A) disconnection becomes possible.

Butadiene is a good diene, but the enamine required is not a good dienophile. An electron-withdrawing group such as a carbonyl or nitro group is preferable: either would do the job. In the event a carboxylic acid that could be converted into the amine by a rearrangement with \((\text{PhO})₂\text{PON}_3\) was used.

The stereochemistry at the ring junction must be cis because the cyclic dienophile can have only a cis double bond. Hydrogenation removes the double bond in the product and shows just how useful the Diels–Alder reaction is for making saturated rings, particularly when there is some stereochemistry to be controlled.

**Stereochemistry of the diene**

This is slightly more complicated as the diene can be cis,cis, or cis,trans (there are two of these if the diene is unsymmetrical), or trans,trans. We shall look at each case with the same dienophile, an acetylene dicarboxylate, as there is then no stereochemistry in the triple bond! Starting with cis,cis-dienes is easy if we make the diene cyclic.
The diene has two sets of substituents—inside and outside. The inside one is the bridging CH$_2$ group and it has to end up on one side of the molecule (above in the last diagram) while the two green hydrogens are outside and remain so. In the final diagram they are below the new six-membered ring. With a trans,trans-diene we simply exchange the two sets of substituents, in this example putting Ph where H was and putting H where the bridging CH$_2$ group was. This is the reaction:

$$\begin{align*}
\text{Ph} + \text{CO}_2\text{Me} & \quad \rightarrow \quad \text{Ph} + \text{CO}_2\text{Me} \\
\text{Ph} + \text{CO}_2\text{Me} & \quad \rightarrow \quad \text{Ph} + \text{CO}_2\text{Me}
\end{align*}$$

The green Ph groups end up where the hydrogens were in the first example—beneath the new six-membered ring—and the hydrogens end up above. It may seem puzzling at first that a trans,trans-diene gives a product with the two phenyls cis. Another way to look at these two reactions is to consider their symmetry. Both have a plane of symmetry throughout and the products must have this symmetry too because the reaction is concerted and no significant movement of substituents can occur. The orange dotted line shows the plane of symmetry, which is at right angles to the paper.

The remaining case—the cis,trans-diene—is rarer than the first two, but is met sometimes. This unsymmetrical diene means the two substituents clearly end up on opposite sides of the new six-membered ring.

The red R group may seem to get in the way of the reaction but, of course, the dienophile is not approaching in the plane of the diene but from underneath. It is difficult to find a convincing example of this stereochemistry as there are so few known, partly because of the difficulty of making E,Z dienes. One good approach uses two reactions you met in Chapter 29 for the control of double-bond geometry. The cis double bond is put in first by the addition of methanol to butadiyne and the trans double bond then comes from LiAlH$_4$ reduction of the intermediate acetylenic alcohol.
The acetate of this alcohol is used in a Diels–Alder reaction with the interesting dienophile DEAD (diethyl azodicarboxylate—in orange). The product is formed in excellent yield and has the *trans* stereochemistry that was predicted. The amide nitrogen atoms are planar, so there is no question of stereochemistry there. DEAD itself can equilibrate rapidly between *E* and *Z* isomers, but the *E* predominates.

![Reaction diagram](image)

Now to the most interesting cases of all, when both the diene and the dienophile have stereochemistry.

**The endo rule for the Diels–Alder reaction**

It is probably easier to see this when both the diene and the dienophile are cyclic. All the double bonds are *cis* and the stereochemistry is clearer. In the most famous Diels–Alder reaction of all time, that between cyclopentadiene and maleic anhydride, there are two possible products that obey all the rules we have so far described. They are the only possible diastereoisomers of the product—although it has four stereogenic centres, any other diastereoisomers would be impossibly strained.

![Stereochemical structures](image)

The two green hydrogen atoms must be *cis* in the product, but now there are two such compounds, known as the *exo* and *endo* products. When the reaction is carried out, the product is, in fact, the *endo* compound. Only one diastereoisomer is formed, and it is the less stable one. How do we know this? Well, for cases in which the Diels–Alder reaction is reversible and therefore under thermodynamic control, the *exo* product is formed instead. The best known example results from the replacement of cyclopentadiene with furan in reaction with the same dienophile.

![Reversible Diels–Alder reaction](image)

Why is the *exo* product the more stable? Look again at these two structures. On the left-hand side of the molecules, there are two bridges across the ends of the new bonds (highlighted in black): a one-C-atom bridge and a two-C-atom bridge. There is less steric hindrance if the smaller (that is, the one-atom) bridge eclipses the anhydride ring.

The *endo* product is less stable than the *exo* product and yet it is preferred in irreversible Diels–Alder reactions—it must be the kinetic product of the reaction. It forms faster because
a bonding interaction between the electron-deficient carbonyl groups of the dienophile and
the developing π bond at the back of the diene lowers the energy of the transition state, lead-
ing to the \( \text{endo} \) product.

The same result is found with acyclic dienes and dienophiles. Normally one diastereoisomer
is preferred—the one with the carbonyl groups of the dienophile closest to the developing π
bond at the back of the diene. Here is an example.

From our previous discussion (it’s a \( \text{trans,trans} \) diene) we expect the two methyl groups to be
cis to each other and the only question remaining is the stereochemistry of the aldehyde
group—up or down? The aldehyde will be \( \text{endo} \)—but which compound is that? The easiest
way to find the answer is to draw the reagents coming together in three dimensions. Here is
one way to do this.

1. Draw the mechanism of the reaction and diagrams of the product to show what you
are trying to decide. Put in the known stereochemistry if you wish. This we have just
done (see above).

2. Draw both molecules in the plane of the paper with the diene on top and the
carbonyl group of the dienophile tucked under the diene so it can be close to the
developing π-bond.

3. Now draw in all the hydrogen atoms on the carbon atoms that are going to become
stereogenic centres, that is, those shown in green here.

4. Draw a diagram of the product. Unfold the molecule to show the six-membered ring.
All the substituents to the right in the previous diagram are on one side of the new
molecule. That is, all the green hydrogen atoms are cis to each other.

5. Draw a final diagram of the product with the stereochemistry of the other substituents
shown too in the usual way. This is the \( \text{endo} \) product of the Diels–Alder reaction.

**Time for some explanations**

We have accumulated rather a lot of unexplained results.

- Why does the Diels–Alder reaction work so well?
- Why must we have a conjugating group on the dienophile?
- Why is the stereochemistry of each component retained so faithfully?
- Why is the \( \text{endo} \) product preferred kinetically?
There is more. The simpler picture we met earlier in this chapter also fails to explain why the Diels–Alder reaction occurs simply on heating while attempted additions of simple alkenes (rather than dienes) to maleic anhydride fail on heating but succeed under irradiation with UV light.

We shall now explain all this in one section using frontier molecular orbitals. Of all the kinds of organic reactions, pericyclic ones are the most tightly controlled by orbitals, and the development of the ideas we are about to expound is one of the greatest triumphs of modern theoretical chemistry. It is a beautiful and satisfying set of ideas based on very simple principles.

The frontier orbital description of cycloadditions

When an ionic cyclization reaction occurs, such as the lactonization at the head of this chapter, one important new bond is formed. It is enough to combine one full orbital with one empty orbital to make the new bond. But in a cycloaddition two new bonds are formed at the same time. We have to arrange for two filled p orbitals and two empty p orbitals to be available at the right place and with the right symmetry. See what happens if we draw the orbitals for the reaction above. We could try the HOMO (\(\pi\)) of the alkene and the LUMO (\(\pi^*\)) of the double bond in the anhydride (as in the margin). This combination is bonding at one end, but antibonding at the other so that no cycloaddition reaction occurs. It obviously doesn’t help to use the other HOMO/LUMO pair, that is the HOMO of the aldehyde and the LUMO of the alkene, as they will have the same mismatched symmetry.

Now see what happens when we replace the alkene with a diene. We shall again use the LUMO of the electron-poor anhydride. Now the symmetry is right because there is a node in the middle of the HOMO of the diene (the HOMO is \(\psi_2\) of the diene) just as there is in the LUMO of the dienophile.

If we had tried the opposite arrangement, the LUMO of the diene (\(\psi_3\)) and the HOMO of the dienophile, the symmetry would again be right. The LUMO of the diene has two nodes and gives the same symmetry as the HOMO of the dienophile, which has no nodes. So either combination is excellent. In fact most Diels–Alder reactions use electron-deficient dienophiles and electron-rich dienes so we prefer the first arrangement. The electron-deficient dienophile has a low-energy LUMO and the electron-rich diene has a high-energy HOMO so this combination gives a better overlap in the transition state. The energy levels will look like this, and the interaction shown in orange is better than the interaction shown in brown because the orbitals are closer in energy.

You may need to remind yourself about the orbitals of conjugated \(\pi\) systems by re-reading Chapter 7.
This is why we usually use dienophiles with conjugating groups for good Diels–Alder reactions. Dienophiles react rapidly with electrophiles because their HOMOs are relatively high in energy, but simple alkenes are not suitable electrophiles because they have relatively high energy LUMOs. The most effective modification we can make is to lower the energy of the alkene’s LUMO by conjugating the double bond with an electron-withdrawing group such as carbonyl or nitro. These are the most common type of Diels–Alder reactions—between electron-rich dienes and electron-deficient dienophiles.

Dimerizations of dienes by cycloaddition reactions

Because dienes have relatively high-energy HOMOs and low-energy LUMOs they should be able to take part in cycloadditions with themselves. And indeed, dienes do dimerize, by a Diels–Alder reaction. One molecule of the diene plays the role of the dienophile. The symmetry is correct for the interaction shown, and we call such reactions (like all the Diels–Alder reactions in this chapter) ‘[4 + 2] cycloadditions’—the numbers referring to the number of atoms of each component taking part in the reaction.

What dienes cannot do is form an eight-membered ring in one step in a [4 + 4] cycloaddition (although this is possible photochemically or with transition metal catalysis, as we shall see later).

You should have expected this failure because the ends of the required orbitals must again have the wrong symmetry, just as they had when we tried the alkene dimerization.

The orbital explanation for endo preference in Diels–Alder reactions

We are going to use a diene dimerization to add more detail to our explanation of the formation of endo products. To make matters even easier we shall look at the dimerization of a cyclic diene—we might almost say the cyclic diene—cyclopentadiene. We introduced the preference for endo products on p. 885 by saying there was a favourable electronic interaction between the conjugating group on the dienophile and the back of the diene.

If we now draw the frontier orbitals in the two components as they come together for the reaction, we can see first of all that the symmetry is correct for bond formation (orbitals shown in black). But we can also see what is happening at the back of the diene (orbitals in green). The symmetry of the orbitals is correct for a bonding interaction at the back of the diene too. This interaction does not lead to the formation of any new bonds but it leaves its imprint in the stereochemistry of the product. The endo product is favoured because of this bonding interaction across the space between the orbitals.
The solvent in the Diels–Alder reaction

We discussed some effects of varying the solvent in Chapter 12, and we shall now introduce a remarkable and useful special solvent effect in the Diels–Alder reaction. The reaction does not need a solvent and often the two reagents are just mixed together and heated. Solvents can be used but, because there are no ionic intermediates, it seems obvious that which solvent is unimportant—any solvent that simply dissolves both reagents will do. This is, in general, true and hydrocarbon solvents are often the best.

However, in the 1980s an extraordinary discovery was made. Water, a most unlikely solvent for most organic reactions, has a large accelerating effect on the Diels–Alder reaction. Even some water added to an organic solvent accelerates the reaction. And that is not all. The endo selectivity of these reactions is often superior to those in no solvent or in a hydrocarbon solvent. Here is a simple example.

The suggestion is that the reagents, which are not soluble in water, are clumped together in oily drops by the water and forced into close proximity. Water is not exactly a solvent—it is almost an anti-solvent! Reactions like this are sometimes called reactions ‘on water’ rather than reactions ‘in water’.

Intramolecular Diels–Alder reactions

When the diene and the dienophile are already part of the same molecule it is not so important for them to be held together by bonding interactions across space and the exo product is often preferred. Indeed, many intramolecular Diels–Alder reactions are governed more by normal steric considerations than by the endo rule.

This reaction happens only because it is intramolecular. There is no conjugating group attached to the dienophile and so there are no orbitals to overlap with the back of the diene. The molecule simply folds up in the sterically most favourable way (as shown in the margin, with the linking chain adopting a chair-like conformation) and this leads to the trans ring junction. You can see this easily in the arrangement of the hydrogen atoms.

In the next example there is a carbonyl group conjugated with the dienophile. Now the less stable cis ring junction is formed because the molecule can fold so that the carbonyl group can enjoy a bonding overlap with the back of the diene. This time the linking chain has to adopt a boat-like conformation.
Intramolecular Diels–Alder reactions may give the endo product or they may not! Be prepared for either exo or endo products or a mixture.

Regioselectivity in Diels–Alder reactions

The compounds that we are now calling dienophiles were the stars of Chapters 22 and 25, where we called them Michael acceptors as they were the electrophilic partners in conjugate addition reactions. Nucleophiles always add to the β carbon atoms of these alkenes because the product is then a stable enolate. Ordinary alkenes do not react with nucleophiles.

\[
\text{OMe} \\ O \\ Nu \\ OMe \\ O \\ Nu \] 

In frontier orbital terms this is because conjugation with a carbonyl group lowers the energy of the LUMO (the π* orbital of the alkene) and at the same time distorts it so that the coefficient on the β carbon atom is larger than that on the α carbon atom. Nucleophiles approach the conjugated alkene along the axis of the large p orbital of the β carbon atom.

These same features can ensure regioselective Diels–Alder reactions. The same orbital of the dienophile is involved and, if the HOMO of the diene is also unsymmetrical, the regioselectivity of the reaction will be controlled by the two largest coefficients bonding together.

So what about distortion of the HOMO in the diene? If a diene reacts with an electrophile, the largest coefficient in the HOMO will direct the reaction. Consider the attack of HBr on a diene. We should expect attack at the ends of the diene because that gives the most stable possible cation—an allyl cation as an intermediate.

\[
\text{OMe} \\ O \\ Nu \\ OMe \\ O \\ Nu \] 

In orbital terms attack occurs at the ends of the diene because the coefficients in the HOMO are larger there. We need simply to look at the HOMO (ψ₂) of butadiene, shown in the margin, to see this. So it is not surprising that the dienes react in the Diels–Alder reaction through their end carbons. But supposing the two ends are different—which reacts now? We can again turn to the reaction with HBr as a guide. Addition of HBr to an unsymmetrical diene will give the more stable of the two possible allyl cations as the intermediate.
In orbital terms, this must mean that the HOMO of the diene is distorted so that the end that reacts has the larger coefficient. When the unsymmetrical diene and the unsymmetrical dienophile combine in a Diels–Alder reaction, the reaction itself becomes unsymmetrical. It remains concerted but, in the transition state, bond formation between the largest coefficients in each partner is more advanced and this determines the regioselectivity of the reaction.

It is not ‘cheating’ to use the regioselectivity of chemical reactions to tell us about the coefficients in orbitals. Chemistry is about using experimental evidence to find out about the theoretical background and not about theory telling us what ought to happen. In fact, computational chemists have calculated the HOMO energies and coefficients of unsymmetrical dienes and have reached the same conclusions.

The simplest way to decide which product will be formed is to draw an ‘ionic’ stepwise mechanism for the reaction to establish which end of the diene will react with which end of the dienophile. Of course this stepwise mechanism is not completely correct but it does lead to the correct orientation of the reagents and you can draw the right mechanism afterwards.

As an example, try a diene with a substituent in the middle. This is the reaction:

\[
\text{MeO} + \text{CN} \xrightarrow{\text{Diels–Alder}} \text{CN} \quad \text{MeO} \quad \text{CN} \quad \text{or} \quad \text{MeO} \quad \text{MeO} \quad \text{CN}
\]

First decide where the diene will act as a nucleophile and where the dienophile will act as an electrophile. This indicates where the largest coefficients of the HOMO and LUMO must lie. The two circles represent those largest coefficients.

Now draw the reagents in the correct orientation for these two ends to combine and draw a concerted Diels–Alder reaction.

This is an important example because an enol ether functional group is present in the product, which can be hydrolysed to a ketone in aqueous acid (Chapter 20).

**Summary of regioselectivity in Diels–Alder reactions**

The important substitution patterns are a diene with an electron-donating group (X) at one end or in the middle and a dienophile with an electron-withdrawing group (Z) at one end. These are the products formed.
A useful mnemonic

If you prefer a rule to remember, try this one.

- The Diels–Alder reaction is a cycloaddition with an aromatic transition state that is ortho and para directing.

You can see that this mnemonic works if you look at the two products above: the first has the two substituents X and Z on neighbouring carbon atoms, just like ortho substituents on a benzene ring, while the second has 1,4-related X and Z just like para substituents. The connection with aromaticity (the ‘aromatic transition state’) simply means that the transition state is cyclic and has six electrons. We have not yet explored the consequences of this, but we will do shortly.

Lewis acid catalysis in Diels–Alder reactions

Where the reagents are unsymmetrical, a Lewis acid that can bind to the electron-withdrawing group of the dienophile often catalyses the reaction by lowering the LUMO of the dienophile still further. It has another important advantage: it increases the difference between the coefficients in the LUMO (a Lewis-acid complexed carbonyl group is a more powerful electron-withdrawing group) and may therefore increase regioselectivity.

This Diels–Alder reaction is useful because it produces a substitution pattern (para) common in natural terpenes (see Chapter 42). But the regioselectivity introduced by one methyl group on the diene is not very great—this reaction gives a 71:29 mixture when the two compounds are heated together at 120°C in a sealed tube. In the presence of the Lewis acid (SnCl₄) the reaction can be carried out at lower temperatures (below 25°C) without a sealed tube and the regioselectivity improves to 93:7.

Regioselectivity in intramolecular Diels–Alder reactions

Just as the stereoselectivity may be compromised in intramolecular reactions, so may the regioselectivity. It may be simply impossible for the reagents to get together in the ‘right’ orientation. The examples below have a very short chain—just three carbon atoms—joining diene to dienophile and so the same regioselectivity is found regardless of the position of the conjugating carbonyl group.

The first example has the ‘right’ orientation (ortho) but the second has the ‘wrong’ orientation (meta). The short tether entails no prospect of any other orientation and, as the reaction is intramolecular, it goes anyway. Notice the lower temperature required for the Lewis acid (ROAlCl₂) catalysed reaction.
The Woodward–Hoffmann description of the Diels–Alder reaction

Kenichi Fukui and Roald Hoffmann won the Nobel prize in 1981 (Woodward died in 1979 and so couldn’t share this prize: he had already won a Nobel prize in 1965 for his work on synthesis) for the application of orbital symmetry to pericyclic reactions. Theirs is an alternative description to the frontier orbital method we have used and you need to know a little about it. They started by considering a more fundamental correlation between the symmetry of all the orbitals in the starting materials and all the orbitals in the products. This is rather too complex for us to cover here, and we shall concentrate only on a summary of the conclusions—the Woodward–Hoffmann rules. The most important of these states:

- **Woodward–Hoffmann rules**
  In a thermal pericyclic reaction the total number of \((4q + 2)s\) and \((4r)a\) components must be odd.

This needs some explanation. A component is a bond or orbital taking part in a pericyclic reaction as a single unit. A double bond is a \(\pi_2\) component. The number 2 is the most important part of this designation and simply refers to the number of electrons. The prefix \(\pi\) tells us the type of electrons. A component may have any number of electrons (a diene is a \(\pi_4\) component) but may not have mixtures of \(\pi\) and \(\sigma\) electrons. Now look back at the rule. Those designations \((4q + 2)\) and \((4r)\) simply refer to the number of electrons in the component where \(q\) and \(r\) are integers. An alkene is a \(\pi_2\) component and so it is of the \((4q + 2)\) kind while a diene is a \(\pi_4\) component and so is of the \((4r)\) kind. You have already seen the importance of \(4n + 2\) numbers in aromaticity; here the significance is closely related.

Now what about the suffixes ‘s’ and ‘a’? The suffix ‘s’ stands for suprafacial and ‘a’ for antarafacial. A **suprafacial** component forms new bonds on the same face at both ends while an **antarafacial** component forms new bonds on opposite faces at both ends. If you find it easier to understand, you can think of the Woodward–Hoffmann rules like this:

- **Woodward–Hoffmann rules: alternative version**
  In an allowed thermal pericyclic reaction this sum:
  
  \[
  \text{number of suprafacial components with 2, 6, or 10 electrons} + \text{number of antarafacial components with 0, 4, or 8 electrons} = \text{an odd number}
  \]

  It’s the number of relevant components that must be odd, not (obviously) the number of electrons, and you must ignore any components which aren’t mentioned in the sum (for example you can have as many suprafacial components with four electrons as you like—they just don’t count).

See how this works for the Diels–Alder reaction. Here is the routine.

1. Draw the mechanism for the reaction (we shall choose a general one).

2. Choose the components. All the bonds taking part in the mechanism must be included and no others.

3. Make a three-dimensional drawing of the way the components come together for the reaction, putting in orbitals at the ends of the components (only!). The orbitals are just unshaded \(p\) orbitals, and do not make up HOMOs or LUMOs nor any particular molecular orbital. Don’t attempt to mix frontier orbital and Woodward–Hoffmann descriptions of pericyclic reactions.
4. Join up the components where new bonds are to be formed. Coloured dotted lines are often used.

5. Label each component ‘s’ or ‘a’ depending on whether new bonds are formed on the same or on opposite sides. In all of the cycloadditions you have seen so far (and indeed the vast majority of those you will ever see), both components react suprafacially.

6. Count the number of $(4q + 2)_s$ and $(4r)_a$ components. If the total count is odd, the reaction is allowed. In this case, there is one $(4q + 2)_s$ component (the alkene) and no $(4r)_a$ components. Total = 1 so it is an allowed reaction. Components of the other symmetry, that is $(4q + 2)_a$ and $(4r)_s$ components, do not count. You can have as many of these as you want.

You may well feel that there is very little to be gained from the Woodward–Hoffmann treatment of the Diels–Alder reaction. It does not explain the *endo* selectivity nor the regioselectivity. However, the Woodward–Hoffmann treatment of other pericyclic reactions (particularly electrocyclic reactions, in the next chapter) is very helpful.

**Trapping reactive intermediates by cycloadditions**

In Chapter 22 you met the remarkable intermediate benzyne. Convincing evidence for the existence of this implausible structure is provided by the fact that it can be trapped in a Diels–Alder reaction. One way of generating benzyne for this purpose is the diazotization of anthranilic acid (2-aminobenzoic acid).

![Image of benzene formation](image)

Benzyne may not look like a good dienophile but it is an unstable electrophilic molecule so it must have a low-energy LUMO (π* of the triple bond). If benzyne is generated in the presence of a diene, efficient Diels–Alder reactions take place. Anthracene gives a specially interesting product with a symmetrical cage structure.

![Image of Diels-Alder reaction with anthracene](image)

It is difficult to draw this mechanism convincingly. The two flat molecules approach each other in orthogonal planes, so that the (orbitals) of the localized π bond of benzyne interact with the p orbitals on the central ring of anthracene.
Another intermediate for which a cycloaddition product provides convincing evidence is the oxyallyl cation. This compound can be made from α,α′-dibromoketones on treatment with zinc metal. The first step is the formation of a zinc enolate (compare the Reformatsky reaction), which can be drawn in terms of the attack of zinc on oxygen or bromine. Now the other bromine can leave as an anion. It could not do so before because it was next to an electron-withdrawing carbonyl group. Now it is next to an electron-rich enolate so the cation is stabilized by conjugation.

![Interactive mechanism for [4 + 3] cycloaddition]

The allyl cation has three atoms but only two electrons so it can take part in cycloadditions with dienes—the total number of electrons is six, just as in the Diels–Alder reaction. This is a [4 + 3] all-suprafacial cycloaddition.

![Interactive mechanism for [4 + 3] cycloaddition]

**Other thermal cycloadditions**

A simple consequence of the Woodward–Hoffmann rules is that cycloadditions involving a total \((4n + 2)\) electrons, if they are all suprafacial, are always allowed: they must always involve an odd number of \((4q + 2)\) components. Such reactions are often referred to as having ‘aromatic transition states’ because of the obvious link with the aromatic requirement for \((4n + 2)\) electrons. Six is the most common \((4n + 2)\) number, but there are also a few cycloadditions involving ten electrons. These are mostly diene + triene, that is, \([4,4,6]\), cycloadditions. Here are a couple of examples.

![Interactive mechanism for [4 + 6] cycloaddition]

In the first case, there is an endo relationship between the carbonyl group and the back of the diene—this product is formed in 100% yield. In the second case Et₂NH is lost from the first product under the reaction conditions to give the hydrocarbon shown. This type of reaction is more of an oddity: by far the most important type of cycloaddition is the Diels–Alder reaction.

**The Alder ‘ene’ reaction**

The Diels–Alder reaction was originally called the ‘diene reaction’ so, when half of the famous team (Kurt Alder) discovered an analogous reaction that requires only one alkene, it was called the Alder ene reaction and the name has stuck. Compare here the Diels–Alder and the Alder ene reactions.
The simplest way to look at the ene reaction is to picture it as a Diels–Alder reaction in which one of the double bonds in the diene has been replaced by a C–H bond (green). The reaction does not form a new ring, the product has only one new C–C bond (shown in black on the product), and a hydrogen atom is transferred across space. Otherwise, the two reactions are remarkably similar.

The ene reaction is rather different in orbital terms. For the Woodward–Hoffmann description of the reaction we must use the two electrons of the C–H bond to replace the two electrons of the double bond in the Diels–Alder reaction, but we must make sure that all the orbitals are parallel, as shown.

The C–H bond is parallel with the p orbitals of the ene so that the orbitals that overlap to form the new $\pi$ bond are already parallel. The two molecules approach one another in parallel planes so that the orbitals that overlap to form the new $\sigma$ bonds are already pointing towards each other. Because the electrons are of two types, $\pi$ and $\sigma$, we must divide the ene into two components, one $\pi_2$ and one $\sigma_2$. We can then have an all-suprafacial reaction with three components.

All three components are of the $(4q + 2)$, type so all count and the total is three—an odd number—so the reaction is allowed. We have skipped the step-by-step approach we used for the Diels–Alder reaction because the two are so similar, but you should convince yourself that you can apply it here.

Now for some real examples. Most ene reactions with simple alkenes are with maleic anhydride. Other dienophiles—or enophiles as we should call them in this context—do not work very well. However, with one particular alkene, the natural pine tree terpene $\beta$-pinene, a reaction does occur with enophiles such as acrylates.

The major interaction between these two molecules is between the nucleophilic end of the exocyclic alkene and the electrophilic end of the acrylate. These atoms have the largest coefficients in the HOMO and LUMO, respectively, and, in the transition state, bond formation between these two will be more advanced than anywhere else. For most ordinary alkenes and enophiles, Lewis acid catalysis to make the enophile more electrophilic, or an intramolecular reaction (or both!), is necessary for an efficient ene reaction.

The ‘ene’ component is delivered to the bottom face of the enone, as its tether is too short for it to reach the top face, and a cis ring junction is formed. The stereochemistry of the third centre is most easily seen by a Newman projection (Chapter 16) of the reaction. In the diagram in the margin we are looking straight down the new C–C bond and the colour coding should help you to see how the stereochemistry follows.
Since the twin roles of the enophile are to be attacked at one end by a C–C double bond and at the other by a proton, a carbonyl group is actually a very good enophile. These reactions are usually called ‘carbonyl ene’ reactions.

The important interaction is between the HOMO of the ene system and the LUMO of the carbonyl group—and a Lewis-acid catalyst can lower the energy of the LUMO still further. If there is a choice, the more electrophilic carbonyl group (the one with the lower LUMO) reacts.

\[ \text{MeO} \quad \text{H} \quad \text{O} \quad \text{O} \quad \text{MeO} \]
\[ \text{MeO} \quad \text{O} \quad \text{H} \]
\[ \text{Ti(OR)}_4 \]
\[ \text{MeO} \quad \text{O} \quad \text{O} \quad \text{H} \]

It may not be obvious that an ene reaction has occurred because of the symmetry of the alkene. The double bond in the product is not, in fact, in the same place as it was in the starting material, as the mechanism shows.

One carbonyl ene reaction is of commercial importance as it is part of a process for the production of menthol used to give a peppermint smell and taste to many products. This is an intramolecular ene reaction on another terpene derivative.

\[ \text{O} \quad \text{H} \quad \text{OH} \]
\[ \text{OH} \]
\[ \text{H}_2/\text{Ni} \]
\[ \text{ZnBr}_2 \]
\[ \text{H} \quad \text{H} \quad \text{Me} \quad \text{O} \quad \text{Me} \quad \text{ZnBr}_2 \]
\[ \text{H} \quad \text{H} \quad \text{H} \quad \text{H} \quad \text{H} \quad \text{H} \]
\[ \text{Me} \quad \text{brown Me equatorial on trans-decalin-like system} \]
\[ \text{Me} \]

It is not obvious what has happened in the first step, but the movement of the alkene and the closure of the ring with the formation of one (not two) new C–C bonds should give you the clue that this is a Lewis-acid-catalysed carbonyl ene reaction.

The stereochemistry comes from an all-chair arrangement in the conformation of the transition state. The methyl group will adopt an equatorial position in this conformation, fixing the way the other bonds are formed. Again, colour coding should make it clearer what has happened.

\[ \text{O} \quad \text{H} \quad \text{ZnBr}_2 \]

\[ \text{Allowed reactions} \]
Because a reaction is ‘allowed’ doesn’t mean that it will happen. It just means it is theoretically possible. In the same way you might be ‘allowed’ to jump off a three metre wall, but you wouldn’t do it.

\[ \text{Interactive mechanism for the intramolecular carbonyl ene reaction} \]

\[ \text{Menthol manufacture} \]
It may seem odd to you to have a chemical process to produce menthol, which would be available naturally from mint plants. This process is now responsible for much of the world’s menthol production so it must make some sort of sense! The truth is that menthol cultivation is wasteful in good land that could produce food crops such as rice while the starting material for menthol manufacture is the same \( \beta \)-pinene we have just met. This is available in large quantities from pine trees grown on poor land for paper and furniture. The earlier stages of the process are discussed in Chapter 41.

\[ \text{Photochemical [2 + 2] cycloadditions} \]
We shall now leave six-electron cycloadditions such as the Diels–Alder and ene reactions and move on to some four-electron cycloadditions. Clearly, four is not a \((4n + 2)\) number, but when we described the Woodward–Hoffman rules on p. 892 we used the term ‘thermally’. All
suprafacial cycloadditions with $4n$ electrons are allowed if the reaction is not thermal (that is, driven by heat energy) but \textit{photochemical} (that is, driven by light energy). Under photochemical conditions, the rules switch such that all the cycloadditions that are not allowed thermally are allowed photochemically. This works because the problem of the incompatible symmetry in trying to add two alkenes together is avoided by converting one of them into the excited state photochemically. First, one electron is excited by the light energy from the $\pi$ to the $\pi^*$ orbital.

Now, combining the excited state of one alkene with the ground state of another solves the symmetry problem. Mixing the two $\pi$ orbitals leads to two molecular orbitals, and two electrons go down in energy while only one goes up. Mixing the two $\pi^*$ orbitals is as good—one electron goes down in energy and none goes up. The result is that three electrons go down in energy and only one goes up. Bonding can occur.

Alkenes can be dimerized photochemically in this way, but reaction between two different alkenes is more interesting. If one alkene is bonded to a conjugating group, it alone will absorb UV light and be excited while the other will remain in the ground state. It is difficult to draw a mechanism for these reactions as we have no simple way to represent the excited alkene. Some people draw it as a diradical (since each electron is in a different orbital); others prefer to write a concerted reaction on an excited alkene marked with an asterisk.

The reaction is stereospecific within each component but there is no \textit{endo} rule—there is a conjugating group but no ‘back of the diene’. The least hindered transition state usually results. The dotted lines on the central diagram simply show the bonds being formed. The two old rings keep out of each other’s way during the reaction and the conformation of the product looks reasonably unhindered.

You may be wondering why the reaction works at all, given the strain in a four-membered ring: why doesn’t the product just go back to the two starting materials? This reverse reaction is governed by the Woodward–Hoffmann rules, just like the forward one, and to go back again the four-membered ring products would have to absorb light. But since they have now lost
their π bonds they have no low-lying empty orbitals into which light can promote electrons (see Chapter 7). The reverse photochemical reaction is simply not possible because there is no mechanism for the compounds to absorb light.

**Regioselectivity in photochemical \([2 + 2]\) cycloadditions**

The observed regioselectivity is shown below. If we had combined the HOMO of the alkene with the LUMO of the enone, as we should in a thermal reaction, we would expect the opposite orientation so as to use the larger coefficients of the frontier orbitals and to maximize charge stabilization in the transition state.

But we are not doing a thermal reaction. If you look back at the orbital diagram on p. 897, you will see that it is the HOMO/HOMO and LUMO/LUMO interactions that now matter in the reactions of the excited state. The sizes of the coefficients in the LUMO of the alkene are the other way round to those in the HOMO. There is one electron in this pair of orbitals—in the LUMO of the enone in fact, as the enone has been excited by the light—so overlap between the two LUMOs (shown in the frame) is bonding and leads to the observed product. The easiest way to work it out quickly is to draw the product you do *not* expect from a normal HOMO/LUMO or curly arrow controlled reaction.

**Thermal \([2 + 2]\) cycloadditions**

Despite what we have told you about allowed cycloadditions, there *are* some thermal \([2 + 2]\) cycloadditions giving four-membered rings. These feature a simple alkene reacting with an electrophilic alkene of a peculiar type. It must have two double bonds to the *same* carbon atom. The most important examples are ketenes and isocyanates. The structures have two π bonds at right angles.

Here are typical reactions of dimethyl ketene to give a cyclobutanone and chlorosulfonyl isocyanate to give a β-lactam.

To understand why these reactions work, we need to consider a new and potentially fruitful way for two alkenes to approach each other. As you saw on p. 886, thermal cycloadditions between two alkenes do not work because the HOMO/LUMO combination is antibonding at one end.

If one alkene turns at 90° to the other, there is a way in which the HOMO of one might bond at both ends to the LUMO of the other. First we turn the HOMO of one alkene so that we are
looking down on the p orbitals. Then we add the LUMO of the other alkene on top of this HOMO and at 90° to it so that there is the possibility of bonding overlap at both ends.

This arrangement looks quite promising until we notice that there is antibonding at the other two corners! Overall there is no net bonding. We can tilt the balance in favour of bonding by adding a p orbital to one end of the LUMO and at a right angle to it so that both orbitals of the HOMO can bond to this extra p orbital. There are now four bonding interactions but only two antibonding. The balance is in favour of a reaction. This is also quite difficult to draw!

Ketenes have a central sp carbon atom with an extra π bond (the C=O) at right angles to the first alkene—perfect for thermal [2 + 2] cycloadditions. They are also electrophilic and so have suitable low-energy LUMOs.

**Ketene [2 + 2] cycloadditions**

Ketene itself is usually made by high-temperature pyrolysis of acetone but some ketenes are easily made in solution. The very acidic proton on dichloroacetyl chloride can be removed even with a tertiary amine and loss of chloride ion then gives dichloroketene in an E1cB elimination reaction. If the elimination is carried out in the presence of cyclopentadiene a very efficient regio- and stereospecific [2 + 2] cycloaddition occurs.

The most nucleophilic atom on the diene adds to the most electrophilic atom on the ketene and the cis geometry at the ring junction comes from the cis double bond of cyclopentadiene. It is impressive that even this excellent diene undergoes no Diels–Alder reaction with ketene as dienophile. The [2 + 2] cycloaddition must be much faster.

**Using the products**

Dichloroketene is convenient to use, but the two chlorine atoms are not usually needed in the product. Fortunately, these can be removed by zinc metal in acetic acid solution. Zinc forms a zinc enolate, which is converted into the ketone by the acid. Repetition removes both chlorine atoms. You saw the reductive formation of a zinc enolate earlier in the chapter (p. 894) and in the Reformatsky reaction (Chapter 26, p. 631).

But what do we do if we want the product of a ketene [4 + 2] cycloaddition? We must use a compound that is not a ketene but that can be transformed into a ketone afterwards—a masked ketene or a ketene equivalent. The two most important types are nitroalkenes and compounds such as the ‘cyanohydrin ester’ in the second example.

**Finding the starting materials for a cyclobutanone synthesis**

The disconnection of a four-membered ring is very simple—you just split in half and draw the two alkenes. There may be two ways to do this.
Both sets of starting materials look all right—the regiochemistry is correct for the first and doesn’t matter for the second. However, we prefer the second because we can control the stereochemistry by using cis-butene as the alkene and we can make the reaction work better by using dichloroketene instead of ketene itself, reducing out the chlorine atoms with zinc.

**Synthesis of β-lactams by [2 + 2] cycloadditions**

Now the disconnections are really different—one requires addition of a ketene to an imine and the other the addition of an isocyanate to an alkene. Isocyanates are like ketenes, but have a nitrogen atom instead of the end carbon atom. Otherwise the orbitals are the same.

And the good news is that both work, providing we have the right substituents on nitrogen. The dichloroacetyl chloride trick works well with imines and, as you ought to expect, the more nucleophilic nitrogen atom attacks the carbonyl group of the ketene so that the regioselectivity is right to make β-lactams.

If both components have one substituent, these will end up trans on the four-membered ring just to keep out of each other’s way. This example has more functionality and the product is used to make β-lactams with antibiotic activity.

You will notice that in both of these examples there is an aryl substituent on the nitrogen atom of the imine. This is simply because N-aryl imines are more stable than their NH analogues (Chapter 11, p. 231).

When we wish to make β-lactams by the alternative addition of an isocyanate to an alkene, a substituent on nitrogen is again required, but for quite a different reason. Because alkenes are only moderately nucleophilic, we need a strongly electron-withdrawing group on the isocyanate that can be removed after the cycloaddition, and the most popular by far is the chlorosulfonyl group. The main reason for its popularity is the commercial availability of chlorosulfonyl isocyanate. It reacts even with simple alkenes.
The alkene's HOMO interacts with the isocyanate's LUMO, and the most electrophilic atom is the carbonyl carbon so this is where the terminal carbon atom of the alkene attacks. The chlorosulfonyl group can be removed simply by hydrolysis under mild conditions via the sulfonic acid.

With a more electron-rich alkene—an enol ether, for example, or the following example with its sulfur analogue, a vinyl sulfide—the reaction ceases to be a concerted process and occurs stepwise. We know this must be the case in the next example because, even though the starting material is an \(E/Z\) mixture, the product has only \(trans\) stereochemistry: it is stereo-selective rather than stereospecific, indicating the presence of an intermediate in which free rotation can take place.

![Diagram of alkene reaction](image)

**Making five-membered rings: 1,3-dipolar cycloadditions**

We have seen how to make four-membered rings by \([2 + 2]\) cycloadditions, how to make six-membered rings by \([4 + 2]\) cycloadditions, and an example of making a seven-membered ring by a \([4 + 3]\) cycloaddition. But what about five-membered rings? What we need is a three-atom, four-electron equivalent of a 'diene' and we can do a Diels–Alder reaction. Such molecules exist: they are called 1,3-dipoles and they are good reagents for \([3 + 2]\) cycloadditions. The molecule containing N and O atoms labelled 'four-electron component' is an example. It has a nucleophilic end \((\text{O}^-)\) and an electrophilic end—the end of the double bond next to the central \(\text{N}^+\). These are 1,3-related, so it is indeed a 1,3-dipole.

![Diagram of 1,3-dipolar cycloaddition](image)

This functional group is known as a nitrone. You could think of it as the \(\text{N}-\text{oxide}\) of an imine. The nitrone gets its four electrons in this way: there are two \(\pi\) electrons in the \(\text{N}=\text{C}\) double bond and the other two come from one of the lone pairs on the oxygen atom. The two-electron component in each of these reactions is an alkene which, in a Diels–Alder reaction, would be called a dienophile. Here it is called a dipolarophile. Simple alkenes (which are bad dienophiles) are good dipolarophiles and so are electron-deficient alkenes. The difference between dienes and 1,3-dipoles is that dienes are nucleophilic and prefer to use their HOMO in cycloadditions with electron-deficient dienophiles while 1,3-dipoles, as their name implies, are both electrophilic and nucleophilic. They can use either their HOMO or their LUMO depending on whether the dipolarophile is electron-deficient or electron-rich.

![Diagram of nitrone reactivity](image)

**N-O functionality**

There are many functional groups containing \(\text{N}-\text{O}\) bonds. Here are a few:

- \(\text{H}^+\text{HO}\): hydroxylamine
- \(\text{R}^+\text{NO}\): nitro compound
- \(\text{R}^-\text{NO}\): nitrate
- \(\text{R}^+\text{NO}\): nitrite
- \(\text{R}^-\text{NO}\): nitroso compound
- \(\text{R}^-\text{NO}\): nitrile oxide
- \(\text{R}^-\text{N}^++\text{OH}\): oxime
- \(\text{R}^-\text{N}^++\text{O}^-\): nitrone
One important nitrone is a cyclic compound that has the structure in the margin and adds to dipolarophiles (essentially any alkene) in a \([3 + 2]\) cycloaddition to give two five-membered rings fused together. The stereochemistry comes from the best approach with the least steric hindrance, as shown. There is no endo rule in these cycloadditions as there is no conjugating group to interact across space at the back of the dipole or dipolarophile. The product shown here is the more stable exo product.

If the alkene is already joined on to the nitrone by a covalent bond, the dipolar cycloaddition is an intramolecular reaction, and one particular outcome may be dictated by the impossibility of the alternatives. In the simple case below, the product has a beautifully symmetrical cage structure. The mechanism shows the only way in which the molecule can fold up to allow a 1,3-dipolar cycloaddition to occur.

The importance of the Diels–Alder reaction is that it makes six-membered rings with control over stereochemistry. The importance of 1,3-dipolar cycloadditions is not so much in the heterocyclic products but in what can be done with them. Almost always, the first formed heterocyclic ring is broken down in some way by carefully controlled reactions. The nitrone adducts we have just seen contain a weak N–O single bond that can be selectively cleaved by reduction. Reagents such as LiAlH₄ or zinc metal in various solvents (acetic acid is popular) or hydrogenation over catalysts such as nickel reduce the N–O bond to give NH and OH functionality without changing the structure or stereochemistry of the rest of the molecule. From the examples above, we get these products:

In each cycloaddition, one permanent C–C and one C–O bond (shown in brown) were made. These were retained while the N–O bond present in the original dipole was discarded. The final product is an amino-alcohol with a 1,3-relationship between the OH and NH groups.

**Linear 1,3-dipoles**

In the Diels–Alder reaction, the dienes had to have an s-cis conformation about the central single bond so that they were already in the shape of the product. Many useful 1,3-dipoles are actually linear and although their 1,3-dipolar cycloadditions look very awkward they still work well. We shall start with the nitrile oxides, which have a triple bond where the nitrone had a double bond.

**Making nitrile oxides**

There are two important routes to these compounds, both of which feature interesting chemistry. Oximes, easily made from aldehydes with hydroxylamine (NH₂–OH), are rather enol-like and can be chlorinated on carbon.
Treatment of the chloro-oxime with base (Et₃N is strong enough) leads directly to the nitrile oxide with the loss of HCl. This is an elimination of a curious kind as we cannot draw a connected chain of arrows for it. We must use two steps—removal of the OH proton and then loss of chloride. It is a γ elimination rather than the more common β elimination.

The other method starts from nitroalkanes and is a dehydration. Inspect the two molecules and you will see that the nitro compound contains one molecule of H₂O more than the nitrile oxide. But how to remove the molecule of water? The reagent usually chosen is phenyl isocyanate (Ph–N=C=O), which removes the molecule of water atom-by-atom to give aniline (PhNH₂) and CO₂. This is probably the mechanism, although the last step might not be concerted, as we have shown.

As you might expect, this [3 + 2] cycloaddition is a reaction involving the HOMO of the alkene and the LUMO of the nitrile oxide so that the leading interaction that determines the structure of the product is the one in the margin. If there is stereochemistry in the alkene, it is faithfully reproduced in the heterocyclic adduct as is usual for a concerted cycloaddition.

Both partners in nitrile oxide cycloadditions can have triple bonds—the product is then a stable aromatic heterocycle called an isoxazole.

Reduction of the N–O bond and the C=N double bond of the nitrile oxide cycloadducts produces useful amino alcohols with a 1,3-relationship between the two functional groups. As the N–O bond is the weaker of the two, it is alternatively possible to reduce just that and leave the C=N bond alone. This gives an imine, which usually hydrolyses during work-up.
Any stereochemistry in the adduct is preserved right through this reduction and hydrolysis sequence: you might like to compare the products with the products of the stereoselective aldol reactions you saw in Chapter 33.

We shall end this section with the illustration of a beautiful intramolecular 1,3-dipolar cycloaddition that was used in the synthesis of the vitamin biotin. Starting at the beginning of the synthesis will allow you to revise some reactions from earlier chapters. The starting material is a simple cyclic allylic bromide that undergoes an efficient SN2 reaction with a sulfur nucleophile. In fact, we don’t know (or care!) whether this is an SN2 or SN2’ reaction as the product of both reactions is the same. This sort of chemistry was discussed in Chapter 24 if you need to check up on it. Notice that it is the sulfur atom that does the attack—it is the soft end of the nucleophile and better at SN2 reactions. The next step is the cleavage of the ester group to reveal the thiolate anion.

**Biotin**

Biotin is an enzyme cofactor that activates and transports CO₂ for use as an electrophile in biochemical reactions.

The nucelophilic thiolate anion does a conjugate addition (Chapter 22) on to a nitroalkene.

Now comes the exciting moment. The nitroalkene gives the nitrile oxide directly on dehydration with PhN=C=O and the cycloaddition occurs spontaneously in the only way it can, given the intramolecular nature of the reaction.
In the margin we show how this reaction works—the nitrile oxide comes up from the underside of the seven-membered ring, pushing the black hydrogen atoms upwards and making all the rings join up in a cis fashion. Next the cycloadduct is reduced completely with LiAlH₄ so that both the N–O and C=N bonds are cleaved. This step is very stereoselective so the C=N reduction probably precedes the N–O cleavage and the hydride has to attack from the outside (top) face of the molecule. These considerations are explored more thoroughly in Chapter 32.

The sulfur-containing ring and the stereochemistry of biotin are already defined. In the seven steps that follow, the rest of the molecule is assembled. The most important is the breaking open of the seven-membered ring by a Beckmann rearrangement (which you will meet in Chapter 36).

**Two very important synthetic reactions: cycloaddition of alkenes with osmium tetroxide and with ozone**

We shall end this chapter with two very important reactions, both of which we have alluded to earlier in the book (Chapter 19). These reactions are very important not just because of their mechanisms, which you must be aware of, but even more because of their usefulness in synthetic chemistry, and in that regard they are second only to the Diels–Alder reaction when considering all the reactions in this chapter. They are both oxidations—one involves osmium tetroxide (OsO₄) and one involves ozone (O₃) and they both involve cycloaddition.

**OsO₄ adds two hydroxyl groups syn to a double bond**

In Chapter 19 we emphasized the stereospecificity of this reaction but now we want to consider the nature of the first step (in the green frame). This is a cycloaddition between the osmium tetroxide and the alkene. You can treat the OsO₄ like a dipole, although it isn't drawn as one because osmium has plenty of orbitals to accommodate four double bonds. The reaction is a [3 + 2] cycloaddition or a 1,3-dipolar cycloaddition, whichever you prefer.
The osmate ester isn’t the required product, and the reaction is usually done in the presence of water (the usual solvent is a t-BuOH-water mixture), which hydrolyses the osmate ester to the diol. Because both oxygen atoms were added in one concerted step during the cycloaddition, their relative stereochemistry must remain syn.

Note that, in the cycloaddition, one arrow stops on osmium and another starts on the other side. Osmium therefore gains a lone pair of electrons and is reduced from Os(VIII) to Os(VI)—the reaction is therefore an oxidation, and it’s one that is very specific to C= C double bonds (as we mentioned in Chapter 23). As written, it would involve a whole equivalent of the expensive, toxic, and heavy metal osmium, but it can be made catalytic by introducing a reagent to oxidize Os(VI) back to Os(VIII). The usual reagent is N-methylmorpholine-N-oxide (NMO) or Fe(III), and typical conditions for an osmylation, or dihydroxylation, reaction are shown in the scheme below.

In behaviour that is typical of a 1,3-dipolar cycloaddition reaction, OsO₄ reacts almost as well with electron-poor as with electron-rich alkenes. OsO₄ simply chooses to attack the alkene HOMO or its LUMO, depending on which gives the best interaction. This is quite different from the electrophilic addition of m-CPBA or Br₂ to alkenes.

A cycloaddition that destroys bonds: ozonolysis

Our last type of cycloaddition is most unusual. It starts as a 1,3-dipolar cycloaddition but eventually becomes a method of cleaving π bonds in an oxidative fashion so that they end up as two carbonyl groups. The reagent is ozone, O₃. Again, you met this reaction in Chapter 19, but we can now show you the full, remarkable details of the reaction mechanism.

Ozone is a symmetrical bent molecule with a central positively charged oxygen atom and two terminal oxygen atoms that share a negative charge. It is a 1,3-dipole and does typical 1,3-dipolar cycloadditions with alkenes. The product is a very unstable compound. The O–O single bond (bond energy 140 kJ mol⁻¹) is a very weak bond—much weaker than the N–O bond (180 kJ mol⁻¹) we have been describing as weak in previous examples—and this heterocycle has two of them. It immediately decomposes—by a reverse 1,3-dipolar cycloaddition.

The products are a simple aldehyde on the left and a new, rather unstable looking molecule—a 1,3-dipole known as a carbonyl oxide—on the right. At least it no longer has any true O–O single bonds (the one that looks like a single bond is part of a delocalized system like the one in ozone). Being a 1,3-dipole, it now adds to the aldehyde in a third cycloaddition step. It might just add back the way it came, but it much prefers to add in the other way round, with the nucleophilic oxyanion attacking the carbon atom of the carbonyl group like this.
This compound—known as an ozonide—is the first stable product of the reaction with ozone. It is the culmination of two 1,3-dipolar cycloadditions and one reverse 1,3-dipolar cycloaddition. It is still not that stable and is quite explosive, so for the reaction to be of any use it needs decomposing. The way this is usually done is with dimethylsulfide or Ph₃P, which attacks the ozonide to give DMSO and two molecules of aldehyde.

The ozonide will also react with oxidizing agents such as H₂O₂ to give carboxylic acids, or with more powerful reducing agents such as NaBH₄ to give alcohols. Here are the overall transformations—each cleaves a double bond—it is called an ozonolysis.

**Summary of cycloaddition reactions**

- A cycloaddition is a one-step ring-forming reaction between two conjugated π systems in which two new σ bonds are formed, joining the two reagents at each end. The mechanism has one step with no intermediates, and all the arrows start on π bonds and go round in a ring.

- The cycloadditions are suprafacial—they occur on one face only of each π system—and for a thermally allowed reaction there should be 4n + 2 electrons in the mechanism, but 4n in a photochemical cycloaddition. These rules are dictated by orbital symmetry.

- Cycloaddition equilibria generally lie over on the right-hand side in a thermal reaction because C–C σ bonds are stronger than C–C π bonds. In a photochemical cycloaddition the product loses its π bonds and therefore its means of absorbing energy. It is therefore the kinetic product of the reaction even if it has a strained four-membered ring.
• The stereochemistry of each component is faithfully reproduced in the product—the reactions are stereospecific—and the relationship between their stereochemistries may be governed by orbital overlap to give an endo product.

In the next chapter we meet two more classes of pericyclic reactions: electrocyclic reactions and sigmatropic rearrangements.

Cycloadditions, the subject of the last chapter, are just one of the three main classes of pericyclic reaction. In this chapter we consider the other two classes: sigmatropic rearrangements and electrocyclic reactions. We will analyse them in a way that is similar to our dealings with cycloadditions.

Sigmatropic rearrangements

The Claisen rearrangement was the first to be discovered

The original sigmatropic rearrangement occurred when an aryl allyl ether was heated without solvent and an ortho-allyl phenol resulted. This is the Claisen rearrangement. The first step in this reaction is a pericyclic reaction of a type that you will learn to call a [3,3]-sigmatropic rearrangement.

![Interactive mechanism for aromatic Claisen rearrangement](image)

This is a one-step mechanism without ionic intermediates or any charges, just like a cycloaddition. The arrows go round in a ring. The difference between this and a cycloaddition is that one of the arrows starts on a \( \sigma \) bond instead of on a \( \pi \) bond. The second step in the reaction is a simple ionic proton transfer to regenerate aromaticity.

Online support. The icon in the margin indicates that accompanying interactive resources are provided online to help your understanding: just type [www.chemtube3d.com/clayden/123](http://www.chemtube3d.com/clayden/123) into your browser, replacing 123 with the number of the page where you see the icon. For pages linking to more than one resource, type 123-1, 123-2 etc. (replacing 123 with the page number) for access to successive links.
How do we know that this is the mechanism? If the allyl ether is unsymmetrical, it turns ‘inside out’ during Claisen rearrangement, as required by the mechanism. Check for yourself that this is right.

The aliphatic Claisen rearrangement also occurs

It was later found that the same sort of reaction occurs without the aromatic ring. This is called either the aliphatic Claisen rearrangement or the Claisen–Cope rearrangement. Here is the simplest possible example.

All these reactions are called sigmatropic because a σ bond appears to move from one place to another during the reaction. This particular reaction is called a [3,3]-sigmatropic rearrangement because the new σ bond has a 3,3 relationship to the old σ bond. You can see this if you number both ends of the old σ bond ‘1’ and count round in both directions to the ends of the new σ bond in the product. You will find that the ends of the new σ bond both have the number ‘3’.

These [3,3]-sigmatropic rearrangements happen through a chair-like transition state, which allows us both to get the orbitals right and to predict the stereochemistry (if any) of the new double bond. The orbitals look something like this.

Note that these do not represent any specific frontier orbitals, they simply show that, in this conformation, the new σ bond is formed from two p orbitals that point directly at each other and that the two new σ bonds are formed from orbitals that are already parallel.

Alkene stereochemistry in the Claisen rearrangement comes from a chair-like transition state

Stereochemistry may arise if there is a substituent on the saturated carbon atom next to the oxygen atom. If there is, the resulting double bond strongly favours the trans (E) geometry. This is because the substituent prefers an equatorial position on the chair transition state.
The substituent \( R \) prefers an equatorial position as the molecule reacts and \( R \) retains this position in the product. The new alkene bond is shown in green. Notice that the trans geometry of the alkene in the product is already there in the conformation chosen by the starting material and in the transition state.

The starting material for these aliphatic Claisen rearrangements consists of ethers with one allyl and one vinyl group. We need now to consider how such useful molecules might be made. There is no problem about the allyl half—allylic alcohols are stable, easily made compounds. But what about the vinyl half? ‘Vinyl alcohol’ is just the enol of acetaldehyde (MeCHO).

\[
\begin{align*}
\text{O} & \quad \text{OH} \\
\text{H} & \quad \text{H} \\
\text{R} & \quad \text{R}
\end{align*}
\]

The solution is to use an acetal of the aldehyde in an acid-catalysed exchange process with the allylic alcohol. It is not necessary to isolate the allyl vinyl ether as long as some of it is formed and rearranges into the final product.

The methanol is distilled off as it is the most volatile of the components in this mixture. A second molecule of methanol is now lost in an acid-catalysed elimination reaction to give the vinyl group.

**The Claisen rearrangement is a general synthesis of \( \gamma,\delta \)-unsaturated carbonyl compounds**

The [3,3]-sigmatropic rearrangement itself can be carried out by heat as part of the same step or as a separate step depending on the compounds. This is a very flexible reaction sequence and can be used for aldehydes (as shown above), ketones, esters, or amides. In each case acetal-like compounds are used—acetals themselves for aldehydes and ketones; orthoesters and orthoaides for the other two (although the orthoaides are often called ‘amide acetals’).
The common feature in the products of these Claisen rearrangements is a \(\gamma,\delta\)-unsaturated carbonyl group. If this is what you need in a synthesis, make it by a Claisen rearrangement.

**Orbital descriptions of \([3,3]\)-sigmatropic rearrangements**

It is possible to give a frontier orbital description of a \([3,3]\)-sigmatropic rearrangement but this is not a very satisfactory treatment because we don’t have two separate reagents recognizing each other across space as we did in cycloadditions. There are three components in these reactions—two non-conjugated \(\pi\) bonds that do have to overlap across space and a \(\sigma\) bond in the chain joining the two \(\pi\) bonds. The Woodward–Hoffmann rules give a more satisfying description and we shall follow the routine outlined on p. 892 for cycloadditions. Note that for stage 3, we can use the three-dimensional diagram we have already made.

First a reminder of the Woodward–Hoffmann rules:

1. **The Woodward–Hoffman rules**

   In a thermal pericyclic reaction the total number of \((4q + 2)\), and \((4r)_a\) components must be odd.

   

1. Draw the mechanism for the reaction (we shall stay with a familiar one).

2. Choose the components. All the bonds taking part in the mechanism must be included and no others.

3. Make a three-dimensional drawing of the way the components come together for the reaction, putting in orbitals at the ends of the components (only!). Note that we have dropped the shading in the orbital from the previous diagrams earlier in the chapter.

4. Join up the components where new bonds are to be formed. Make sure you join orbitals that are going to form new bonds.

5. Label each component \(s\) or \(a\) depending whether new bonds are formed on the same or on opposite sides. See below for the \(\sigma\) bond symmetry.
6. Add up the number of \((4q + 2)\), and \((4r)\) components. If the sum is odd, the reaction is allowed. Here there is:

- **one** \((4q + 2)\) component (one alkene) and
- **no** \((4r)\) components.

Total = 1, so this is an allowed reaction. As you saw in Chapter 34 (p. 893), the \(\pi_{2a}\) and \(\sigma_{2a}\) components have irrelevant symmetry and are not counted.

One new aspect of orbital symmetry has appeared in this diagram—how did we deduce a \(\sigma\) or \(s\) symmetry in the way the \(\sigma\) bond reacted? For \(\pi\) bonds it is simple—if both bonds are formed on the same side of the old \(\pi\) bond, it has reacted suprafacially; if on opposite sides, antarafacially.

With a \(\sigma\) bond the symmetry is not so obvious. We want to know if it does the **same** thing at each end (s) or a **different** thing (a). But what is the ‘thing’ it does? It reacts using the large lobe of the sp\(^3\) orbital (retention) or the small lobe (inversion). If it reacts with retention at both ends or inversion at both ends, it reacts suprafacially, while if it reacts with retention at one end and inversion at the other, it reacts antarafacially. There are four possibilities.

- **σ bond reacting suprafacially**
  - retention at both ends
  - inversion at both ends

- **σ bond reacting antarafacially**
  - inversion at one end
  - retention at the other end

In the routine above, we chose to use our \(σ\) bond so that we got inversion at one end and retention at the other. That was why we identified it as an antarafacial component. If we had chosen another style we should have got different descriptions of the components, but the reaction would still have been allowed, for example changing just one connecting line, as in the margin, changes the symmetry of the \(σ\) bond so that it becomes a \(σ_{2a}\) component but it also changes the symmetry of one of the \(π\) bonds so that it becomes a \(π_{2a}\) component. The net result is still only one component of the Woodward–Hoffmann symmetry, the sum is still 1, and the reaction still allowed.

### The direction of [3,3]-sigmatropic rearrangements

Orbital symmetry tells us that [3,3]-sigmatropic rearrangements are allowed but says nothing about which way they will go. They are allowed in either direction. So why does the Claisen–Cope rearrangement always form the carbonyl-containing product? Think back to our discussion on enols (Chapter 20) and you may recall that the combination of a carbonyl group and a C–C \(σ\) bond made the keto form more stable than the enol form with its combination of a C=C \(π\) bond and a C–O \(σ\) bond. The same is true here. It is the stability of the carbonyl group that drives the reaction to the right.

### Directing the Cope rearrangement by the formation of a carbonyl group

The Cope rearrangement is a [3,3]-sigmatropic rearrangement with only carbon atoms in the ring. In its simplest version it is not a reaction at all. The starting material and the product are the same.

We can drive this reaction too by the formation of a carbonyl group if we put an OH substituent in the right place.
The product of the sigmatropic step is the enol of the final product. It turns out that the reaction is accelerated if the starting alcohol is treated with base (KH is the best) to make the alkoxide. The product is then the potassium enolate, which is more stable than the simple potassium alkoxide starting material. As the reaction proceeds, conjugation is growing between $O^-$ and the new $\pi$ bond.

Some remarkable compounds can be made by this method. One of the strangest—a ‘bridgehead’ alkene—was made by a potassium alkoxide-accelerated Cope rearrangement in which a four-membered ring was expanded into an eight-membered ring containing a trans double bond (shown in green).

A combination of an oxygen atom in the ring and another one outside the ring is very powerful at promoting [3,3]-sigmatropic rearrangements and easy to arrange by making the lithium enolate of an ester of an allylic alcohol.

Sometimes it is better to convert the lithium enolate into the silyl enol ether before heating to accomplish the [3,3]-sigmatropic rearrangement. In any case, both products give the unsaturated carboxylic acid on work-up.

This reaction is known as the Ireland–Claisen rearrangement as it was a variation of the Claisen rearrangement invented by R. E. Ireland in the 1970s and widely used since. If the substituents are suitably arranged, it shows the same $E$ selectivity as the simple Claisen rearrangement and for the same reason.
In some cases simple Cope rearrangements without any oxygen atoms at all can be directed by an unstable starting material or a stable product. The instability might be strain and the stability might simply be more substituents on the double bonds. In the next reaction the driving force is the breaking of a weak σ bond in a three-membered ring. This reaction goes in 100% yield at only just above room temperature, so it is very favourable. In the second example, the trisubstituted double bonds inside the five-membered rings of the product are more stable than the exomethylene groups in the starting material.

**An industrial synthesis of citral**

‘Citral’ is a key intermediate in the synthesis of vitamin A, and it is manufactured by a remarkable process that involves two successive [3,3]-sigmatropic rearrangements, a Claisen followed by a Cope. The allyl vinyl ether needed for the Claisen rearrangement is an enol ether of an unsaturated aldehyde with an unsaturated alcohol. The two starting materials are themselves derived from a common precursor, making this a most efficient process! Heating the enol ether promotes [3,3]-sigmatropic rearrangement propelled by the formation of a carbonyl group.

But the product of this rearrangement is now set up for a second [3,3]-sigmatropic rearrangement, this time made favourable by a shift into conjugation and the formation of two trisubstituted double bonds from two terminal ones. Overall, the prenyl group walks from one end of the molecule to the other, inverting twice as it goes.

**Seaweed sex censored by a sigmatropic shift**

In order to reproduce, the female gametes of marine brown algae must attract mobile male gametes. This they do by releasing a pheromone, long thought to be the cycloheptadiene ectocarpene. In 1995 results were published that suggested that, in fact, the pheromone was a cyclopropane, and that ectocarpene was ineffective as a pheromone.

How had the confusion arisen? Well, the remarkable thing is that the cyclopropyl pheromone inactivates itself with a half-life of several minutes at ambient temperature, by [3,3]-sigmatropic rearrangement to the cycloheptadiene, driven by release of strain from the three-membered ring. This not only confused the earlier pheromone chemists, but it also provides a marvellously precise way for the algae to signal their presence and readiness for reproduction without saturating the sea water with meaningless pheromone.
Applications of \([3,3]\)-sigmatropic rearrangements using other elements

There is no need to restrict our discussion to carbon and oxygen atoms. We shall finish this section with two useful reactions that use other elements. You met the most famous synthesis of indoles in Chapter 30—the Fischer indole synthesis—and we can now look in more detail at the key step of this remarkable reaction. Condensation of phenylhydrazine with a ketone in slightly acidic solution gives a phenylhydrazone.

\[
\text{phenylhydrazine} + \text{ketone} \xrightarrow{\text{slightly acidic solution}} \text{phenylhydrazone}
\]

If the ketone is enolizable, this imine is in equilibrium with the corresponding enamine. The important bonds are given in black in the diagram. The enamine is ideally set up for a \([3,3]\)-sigmatropic rearrangement in which the \(\sigma\) bond to be broken is the weak \(N-N\) \(\sigma\) bond and one of the \(\pi\) bonds is in the benzene ring.

\[
\text{phenylhydrazone} \xrightarrow{[3,3]} \text{an enamine} \xrightarrow{\text{enamine}} \text{indole}
\]

The product is a highly unstable double imine. But aromaticity is immediately restored and a series of proton shifts and \(C-N\) bond formation and cleavage reactions give the aromatic indole.

That was a \([3,3]\)-sigmatropic reaction involving two nitrogens. There follows one with two oxygens and a chromium atom. When tertiary allylic alcohols are oxidized with \(\text{CrO}_3\) in acid solution, no direct oxidation can take place, but a kind of conjugate oxidation occurs.

\[
\text{RLi} + \text{OH} \xrightarrow{\text{RLi, CrO}_3, H^+} \text{RCr} + H_2O
\]

The first step in \(\text{Cr(VI)}\) oxidations can take place to give a chromate ester but this intermediate has no proton to lose so it transfers the chromate to the other end of the allylic system, where there is a proton. The chromate transfer can be drawn as a \([3,3]\)-sigmatropic rearrangement. The final step is the normal oxidation in which chromium drops down from orange \(\text{Cr(VI)}\) to \(\text{Cr(IV)}\) and eventually by disproportionation to green \(\text{Cr(III)}\).
[2,3]-Sigmatropic rearrangements

All [3,3]-sigmatropic rearrangements have six-membered cyclic transition states. It is no accident that the size of the ring is given by the sum of the two numbers in the square brackets and this is universally the case for sigmatropic rearrangements. We are now going to look at [2,3]-sigmatropic rearrangements so we will be needing five-membered cyclic transition states. There is a problem here. You cannot draw three arrows going round a five-membered ring without stopping or starting on an atom, not a bond. This can be OK if the atom is a carbanion.

The starting material is a benzyl allyl ether and undergoes [2,3]-sigmatropic rearrangement to make a new C–C σ bond at the expense of a C–O σ bond—a bad bargain this as the C–O bond is stronger. The balance is tilted by the greater stability of the oxyanion in the product than of the carbanion in the starting material. The new bond has a 2,3 relationship to the old and the transition state is a five-membered ring.

The transition state can be quite chair-like so that the new π bond will be trans if it has a choice. There will be a choice if the ether has been made from a substituted allyl alcohol.

We cannot draw a complete chair as we haven’t got a six-membered ring, but the part that is to become the new π bond can be in a chair-like part of the five-membered ring. The substituent R prefers an equatorial position and the resulting trans arrangement of the groups is outlined in green.

We can use the same conformational diagram to show how the orbitals overlap as the new bond is formed. When we come to use the Woodward–Hoffmann rules on these [2,3]-sigmatropic rearrangements, we find something new. We have a π bond and a σ bond and a carbanion. How are we to represent a carbanion (or a carbocation) that is just a p orbital on an atom? The new symbol we use for a simple p orbital is ω (lower case omega).
A carbanion is an $\omega^2$ component and a carbocation is an $\omega^0$ component as it has zero electrons. If the two new bonds are formed to the same lobe of the p orbital of the carbanion, we have an $\omega^2_s$ component, but if they are formed to different lobes we have an $\omega^2_a$ component.

Without going through the whole routine again, the [2,3]-sigmatropic rearrangement we have been discussing can be described as an $\omega^2_s + \omega^2_s + \omega^a$ reaction. There is one $(4q + 2)_s$ and no $(4r)_a$ component so the reaction is thermally allowed.

**[2,3]-Sigmatropic rearrangements with S and Se**

There are many [2,3]-sigmatropic rearrangements involving a variety of heteroatoms as well as carbon. The mechanism is common with elements that are prepared to change their oxidation state by two so that an arrow can both start and finish on that atom. The examples in this section involve sulfur and selenium, which can both form stable compounds at three oxidation states: S or Se(II), S or Se(IV), and S or Se(VI).

![Interactive mechanism for the [2,3]-sigmatropic shift of sulfoxides](image)

Reaction of an allylic alcohol with PhSCI gives an unstable sulfenate ester that rearranges on heating to an allylic sulfoxide by a [2,3]-sigmatropic rearrangement involving both O and S. Notice that arrows both start and stop on the sulfur atom, which changes from S(II) to S(IV) during the reaction. The new functional group with an S=O bond is a sulfoxide, and this is a good way of making allylic sulfoxides. The product forms an anion stabilized by sulfur, which can be alkylated.

We have said that all these sigmatropic rearrangements are reversible but now we can prove it. If this product is heated in methanol with a nucleophile such as (MeO)$_3$P (trimethylphosphite), which has a liking for sulfur, the [2,3]-sigmatropic rearrangement runs backwards and a sulfenate ester is again formed.

This is an unfavourable reaction because the equilibrium lies over on the sulfoxide side. But the nucleophile traps the sulfenate ester and the methanol ensures that the alkoxide ion formed is immediately protonated so that we get another allylic alcohol.

So what is the point of going round in circles like this? The net result is the alkylation of an allylic alcohol in a position where alkylation would not normally be considered possible.
A related reaction of selenium in its +4 oxidation state (as selenium dioxide, SeO₂) allows us to make allylic alcohols and enals from simple alkenes. The overall reaction is the simple oxidation shown in the margin, but the route by which the compound gets there involves two successive pericyclic reactions.

Selenium dioxide will react with alkenes in a [4 + 2] cycloaddition reminiscent of the ene reaction.

\[
\text{R} = \text{SeO}_2 \rightarrow \text{R} + \text{SeO}_2 \quad \text{[4 + 2]}
\]

The initial product is an allylic seleninic acid—and just like an allylic sulfoxide (but more so because the C–Se bond is even weaker) it undergoes allylic rearrangement to give an unstable compound that rapidly decomposes to an allylic alcohol. In some cases, particularly this most useful oxidation of methyl groups, the oxidation continues to give an aldehyde or ketone.

Overall, CH₃ has been replaced by CH₂OH or CH=O in an allylic position, a transformation similar to the allylic bromination reaction with NBS that you met in Chapter 24, but with a very different mechanism. The by-product of the oxidation is a selenium(II) compound, and it can be more practical to carry out the reaction with only a catalytic amount of SeO₂, with a further oxidizing agent, t-butyl hydroperoxide, to reoxidize the Se(II) after each cycle of the reaction. This eliminates the need to get rid of large amounts of selenium-containing products, which are toxic and usually smelly.

### [1,5]-Sigmatropic hydrogen shifts

When one of the numbers in square brackets is ‘1’, the old and new σ bonds are to the same atom, so we are dealing with the migration of a group around a conjugated system. In the case of a [1,5]-sigmatropic rearrangement the transition state is a six-membered ring (remember—just add together the numbers in square brackets). There is an important example in the margin. Let us first check that this is indeed a [1,5]-sigmatropic rearrangement by numbering the position of the new σ bond with respect to the old. Note that we must go the long way round the five-membered ring because that is the way the mechanism goes.

It is a [1,5]-sigmatropic rearrangement. The figure ‘1’ in the square brackets shows that the same atom is at one end of the new σ bond as was at one end of the old σ bond. One atom has moved in a 1,5 manner and these are often called [1,5]-sigmatropic shifts. This is often abbreviated to [1,5]H shift to show which atom is moving. This particular example is important because sadly it prohibits most attractive idea. The aromatic cyclopentadienyl anion is easily formed, stable, and readily alkylated. This sequence of alkylation and Diels–Alder reaction looks very good.

But sadly this sequence is, in fact, no good at all. A mixture of three Diels–Alder adducts is usually obtained resulting from addition to the three cyclopentadienes present in solution as
the result of rapid [1,5]H shifts. The one drawn above is a minor product because there is more of the other two dienes, which have an extra substituent on the double bonds.

An excellent example comes from the intramolecular Diels–Alder reactions explored by Dreiding in 1983. One particular substituted cyclopentadiene was made by a fragmentation reaction (see Chapter 36). It might have been expected to give a simple Diels–Alder adduct.

There is nothing wrong with this reaction—indeed, the product looks beautifully stable—but it is not formed because the [1,5]H shift is too quick and gives a more stable cyclopentadiene with more substituents on a double bond. Then it does the Diels–Alder reaction.

Notice that in these compounds the ketone is not conjugated to any of the alkenes and so does not influence the reaction. If we increase the reactivity of the dienophile by putting an ester group in conjugation with it, most of the compound does the Diels–Alder reaction before it does the [1,5]H shift.

**Orbital description for the [1,5]H sigmatropic shift**

It is equally satisfactory to use frontier orbitals or the Woodward–Hoffmann rules for these reactions. We can take the diene as one component (HOMO or LUMO or π) and the C–H bond as the other (LUMO or HOMO or σ). Let us start by using the LUMO of the diene (ψ₃) and the HOMO of the C–H bond (its filled σ orbital), as shown in the margin. If the circle around the H atom surprised you, perhaps it will also remind you that hydrogen has only a 1s orbital, which is spherical. You can probably see already that all the orbitals are correctly lined up for the reaction.

The hydrogen atom slides across the top face of the planar cyclopentadiene ring. We call this a suprafacial migration, meaning that the migrating group leaves from one face of the π system and rejoins that same face (the top face in this example). Antarafacial migration would mean leaving the top face and rejoining the bottom face—a clear impossibility here.
If you use the Woodward–Hoffmann rules, you need to note that the hydrogen atom must react with retention. The 1s orbital is spherically symmetrical and has no node, so wherever you draw the dotted line from that orbital it always means retention. Choosing the components is easy—the diene is a \( \pi \) and the C–H bond a \( \sigma \) component.

The easiest way to join them up is to link the hydrogen atom’s 1s orbital to the top lobe of the \( \pi \) orbital at the back of the diene and the black sp\(^3\) orbital to the top lobe at the front of the diene. This gives us \( \pi \) and \( \sigma \) components and there is one \( 4q + 2 \), and no \( 4r \), components so the sum is odd and the reaction is allowed. Both approaches give us the same picture—a suprafacial migration of the hydrogen atom with (inevitably) retention at the migrating group.

These [1,5]-sigmatropic shifts are not restricted to cyclopentadienes. In Chapter 34 we bemoaned the lack of Diels–Alder reactions using \( E,Z \) dienes. One reason for the shortage of examples is that such dienes undergo [1,5]H shifts rather easily and mixtures of products result.

The consequences of orbital symmetry for sigmatropic hydrogen shifts are simple. In thermal reactions, [1,5]H shifts occur suprafacially but [1,3]H and [1,7]H shifts must be antarafacial. Antarafacial [1,3]H shifts are impossible, even though they are allowed, because a rigid three-carbon chain is too short to allow the H atom to transfer from the top to the bottom—the H atom just can’t reach. This is just as well, as otherwise double bonds would just wander around molecules by repeated [1,3]H shifts.

When we come to [1,7]H shifts, the situation is different. Now the much longer chain is just flexible enough to allow antarafacial migration. The hydrogen atom leaves the top side of the triene and adds back in on the bottom side. The diagram shows this in orbital terms: the LUMO of hexatriene has three nodes. Antarafacial [1,7]H migration is allowed and possible.

### Photochemical [1,n] H sigmatropic shifts follow the opposite rules

As you should by now expect, all this is reversed in photochemical reactions. The margin shows an example of a [1,7]H shift that cannot occur antarafacially because the molecule is a rigid ring, but that can and does occur photochemically in a suprafacial manner.

A [1,7]H shift occurs in the final stages of the human body’s synthesis of vitamin D from cholesterol. Here is the last step of the biosynthesis.
This step happens spontaneously, without the need for light, so the [1,7]H shift must be antarafacial. That’s no problem in this triene system—there is enough flexibility for the hydrogen atom to migrate from the top to the bottom face.

Why, then, does the body famously need sunlight to make vitamin D? The reason is the previous step, which can only occur when light shines on the skin.

This ring opening is clearly pericyclic—the electrons go round in a ring, and the curly arrows could be drawn either way—but it is neither a cycloaddition (only one π system is involved) nor a sigmatropic rearrangement (a σ bond is broken rather than moved). It is, in fact, a member of the third and last kind of pericyclic reaction, an electrocyclic reaction.

**Electroyclic reactions**

In an electrocyclic reaction a ring is always broken or formed. Rings may, of course, be formed by cycloadditions as well, but the difference with electrocyclic reactions is that just one new σ bond is formed (or broken) across the ends of a single conjugated π system. In a cycloaddition, two new σ bonds are always formed (or broken), and in a sigmatropic rearrangement one σ bond forms while one breaks.

- The types of pericyclic reactions are distinguished by the number of σ bonds made or broken

One of the simplest electrocyclic reactions occurs when hexatriene is heated to 500 °C. It is a pericyclic reaction because the electrons go round in a ring (you could equally draw the arrows going the other way); it’s electrocyclic because a new σ bond is formed across the ends of a π system. The reaction goes because the σ bond that is formed is stronger than the π bond that is lost.

The opposite is true for the electrocyclic opening of cyclobutene—ring strain in the four-membered ring means that the reverse (ring-opening) reaction is preferred to ring closure.

In one famous case, the release of ring strain is almost exactly counterbalanced by the formation of a σ bond at the expense of a π bond. Cycloheptatriene exists in equilibrium with a bicyclic isomer known as norcaradiene. Usually cycloheptatriene is the major component of the equilibrium, but the norcaradiene structure is favoured with certain substitution patterns.
Rules for electrocyclic reactions

Whether they go in the direction of ring opening or ring closure, electrocyclic reactions are subject to the same rules as all other pericyclic reactions. With most of the pericyclic reactions you have seen so far, we have given you the choice of using either HOMO–LUMO reasoning or the Woodward–Hoffmann rules. With electrocyclic reactions, you really have to use the Woodward–Hoffmann rules because (at least for the ring closures) there is only one molecular orbital involved.

Electrocyclic reactions

- An electrocyclic reaction is the formation of a new $\sigma$ bond across the ends of a conjugated polyene or the reverse.

It is important that you do not confuse electrocyclic reactions with pericyclic reactions. Pericyclic is the name for the whole family of reactions involving no charged intermediates in which the electrons go round the outside of the ring. Electroyclic reactions, cycloadditions, and sigmatropic rearrangements are the three main classes of pericyclic reactions.

Let’s start with the hexatriene ring closure from the beginning of this section, first looking at the orbitals and then following the same procedure that we taught you for cycloadditions and sigmatropic rearrangements to see what the Woodward–Hoffmann rules have to say about the reaction.

Hexatriene is, of course, a $6\pi$ electron ($\pi_6$) conjugated system and, on forming cyclohexadiene, the end two orbitals must rotate through $90^\circ$ to form a $\sigma$ bond.

So, now for the Woodward–Hoffmann treatment.

1. Draw the mechanism for the reaction.

2. Choose the components. All the bonds taking part in the mechanism must be included and no others.

3. Make a three-dimensional drawing of the way the components come together for the reaction, putting in orbitals at the ends of the components (only!).

4. Join up the components where new bonds are to be formed. Make sure you join orbitals that are going to form new bonds.

5. Label each component s or a depending on whether new bonds are formed on the same or on opposite sides. We called this reaction ‘s’ because the top halves of the two $\pi$ orbitals join together.

6. Add up the number of $(4q + 2)$, and $(4r)_a$ components. If the sum is odd, the reaction is allowed. Here there is one $(4q + 2)$ component and no $(4r)_a$ components. Total = 1 so this is an allowed reaction.

We can give the same treatment to the cyclobutene ring-opening reaction—the Woodward–Hoffmann rules tell us nothing about which way the reaction will go, only if the reaction is allowed, and it is usually easier with electrocyclic reactions to consider the ring-closing reaction even if ring opening is favoured thermodynamically. This is the process we need to consider:

Reminder. In a thermal pericyclic reaction the total number of $(4q + 2)$, and $(4r)_a$ components must be odd.
And the Woodward–Hoffmann treatment again.

1. Draw the mechanism for the reaction.

2. Choose the components. All the bonds taking part in the mechanism must be included and no others.

3. Make a three-dimensional drawing of the way the components come together for the reaction, putting in orbitals at the ends of the components (only!).

4. Join up the components where new bonds are to be formed. Make sure you join orbitals that are going to form new bonds.

5. Label each component s or a depending on whether new bonds are formed on the same or on opposite sides.

6. Add up the number of \((4q + 2)_s\) and \((4r)_a\) components. If the sum is odd, the reaction is allowed. There are no \((4q + 2)_s\) components and no \((4r)_a\) components. Total = 0 so this is a disallowed reaction.

Oh dear! We know that the reaction works, so something must be wrong. It certainly isn’t Woodward and Hoffmann’s Nobel-prize-winning rules—it’s our way of drawing the orbital overlap that is at fault. We were fine up to stage 3 (we had no choice till then)—but see what happens if we make the orbitals overlap in a different way.

1. As before.

2. As before.

3. Make a three-dimensional drawing of the way in which the components come together for the reaction, putting in orbitals at the ends of the components (only!).

4. Join up the components where new bonds are to be formed. Make sure you join orbitals that are going to form new bonds.

5. Label each component s or a depending on whether new bonds are formed on the same or on opposite sides.

6. Add up the number of \((4q + 2)_s\) and \((4r)_a\) components. If the sum is odd, the reaction is allowed. There are no \((4q + 2)_s\) components and one \((4r)_a\) component. Total = 1 so this is an allowed reaction.

Now it works! In fact, extension of this reasoning to other electrocyclic reactions tells you that they are all allowed—provided you choose to make the conjugated system react with itself suprafacially for \((4n + 2)\) \(\pi\) systems and antarafacially for \((4n)\) \(\pi\) systems. This may not seem particularly informative, since how you draw the dotted line has no effect on the reaction product in these cases. But it can make a difference. Here is the electrocyclic ring closure of an octatriene, showing the product from (a) suprafacial reaction and (b) antarafacial reaction.
**Conrotatory and disrotatory reactions**

Whether the reaction is supra- or antarafacial ought to be reflected in the relative stereochemistry of the cyclized products—and indeed it is. The reaction above gives solely the diastereoisomer on the left, with the methyl groups syn—clear proof that the reaction is suprafacial. This is a difficult result to explain without the enlightenment provided by the Woodward–Hoffmann rules! This electrocyclic cyclobutene ring opening also gives the product as a single stereoisomer.

![Diagram](image)

Again, if we draw the reverse reaction, we can see that the reaction required has to be antarafacial for the stereochemistry to be right.

We have drawn little green arrows on the diagrams to show how the methyl groups move as the new σ bonds form. For the allowed suprafacial reaction of the 6π electron system they rotate in opposite directions so the reaction is called **disrotatory** (yes, they both go up, but one has to rotate clockwise and one anticlockwise) while for the allowed antarafacial reaction of the 4π electron system they rotate in the same direction so the reaction is called **conrotatory** (both clockwise as drawn, but they might equally well have both gone anticlockwise).

We can sum up the course of all electrocyclic reactions quite simply using these words.

**Rules for electrocyclic reactions**

- All electrocyclic reactions are allowed.
- Thermal electrocyclic reactions involving \((4n + 2)\) π electrons are **disrotatory**.
- Thermal electrocyclic reactions involving \((4n)\) π electrons are **conrotatory**.
- In **conrotatory** reactions the two groups rotate in the same turning sense: both clockwise or both anticlockwise.
- In **disrotatory** reactions, one group rotates clockwise and one anticlockwise.

This rotation is the reason why you must carefully distinguish electrocyclic reactions from all other pericyclic reactions. In cycloadditions and sigmatropic rearrangements there are small rotations as bond angles adjust from 109° to 120° and vice versa, but in electrocyclic reactions rotations of nearly 90° are required as a planar polyene becomes a ring or vice versa. These rules follow directly from application of the Woodward–Hoffmann rules—you can check this for yourself.

**Electroyclic reactions in nature: the endiandric acids**

A beautiful example of electrocyclic reactions at work is provided by the chemistry of the endiandric acids. This family of natural products, of which endiandric acid D is one of the simplest, is remarkable in being racemic—most chiral natural products are enantiomerically pure (or at least enantiomerically enriched) because they are made by enantiomerically pure enzymes (we discuss all this in Chapter 42). So it seemed that the endiandric acids were formed by non-enzymatic cyclization reactions, and in the early 1980s their Australian discoverer, Black, proposed that their biosynthesis might involve a series of electrocyclic reactions, starting from an acyclic polyene precursor.
What made his proposal so convincing was that the stereochemistry of the endiandric acid D is just what you would expect from the requirements of the Woodward–Hoffmann rules. The first step from the precursor is an 8π electrocyclic reaction, and would therefore be conrotatory.

This sets up a new 6π system, which can undergo an electrocyclic reaction in disrotatory fashion. Because there are already chiral centres in the molecule, there are, in fact, two possible diastereoisomeric products from this reaction, both arising from disrotatory cyclization. One is endiandric acid D; one is endiandric acid E.

Of course, this was only a hypothesis—until in 1982 K.C. Nicolaou’s group synthesized the proposed endiandric acid precursor polyene—and in one step made both endiandric acids D and E, plus endiandric acid A, which arises from a further pericyclic reaction—an intramolecular Diels–Alder cycloaddi-

**Photochemical electrocyclic reactions**

After your experience with cycloadditions and sigmatropic rearrangements, you will not be surprised to learn that, in photochemical electrocyclic reactions, the rules regarding conrotatory and disrotatory cyclizations are reversed.
We can now go back to the reaction that introduced this section—the photochemical electrocyclic ring opening of ergosterol to give provitamin D$_2$. By looking at the starting material and product we can deduce whether the reaction is conrotatory or disrotatory.

It's clearly conrotatory, and a little more thought will tell you why it has to be—a disrotatory thermal $6\pi$ cyclization would put an impossible trans double bond into one of the two six-membered rings. Vitamin D deficiency is endemic in those parts of the world where sunlight is scarce for many months of the year—and all because of orbital symmetry.

**Cations and anions**

What we have just been telling you should convince you that the two reactions below are electrocyclic reactions, not least because the stereochemistry reverses on going from thermal to photochemical reaction.

They are examples of what is known, after its Russian discoverer, as the Nazarov cyclization. In its simplest form, the Nazarov cyclization is the ring closure of a doubly $\alpha,\beta$-unsaturated ketone to give a cyclopentenone. Nazarov cyclizations require acid, and protonation of the ketone sets up the conjugated $\pi$ system required for an electrocyclic reaction.

One of the five $\pi$ orbitals involved is empty—so the cyclization is a $4\pi$ electrocyclic reaction, and the orbitals forming the new $\sigma$ bond must interact antarafacially. Loss of a proton and tautomerism gives the cyclopentenone.
The example below confirms that the reaction is thermally conrotatory and photochemically disrotatory.

Dienyl cations and dienyl anions both undergo electrocyclic ring closure—a nice example occurs when this cyclooctadiene is deprotonated with butyllithium. There are still five $\pi$ orbitals involved in the cyclization, but now there are six $\pi$ electrons, so the reaction is disrotatory.

In this case, it is the conrotatory photochemical cyclization that is prevented by strain (it was tried—cyclooctadienyl anion is stable for at least a week at –78 °C in broad daylight) as the product would be a 5,5 trans-fused system. The same strain prevents thermal electrocyclic ring closure of cyclooctadienyl cations.

All electrocyclic reactions are allowed

It would be a good point here to remind you that, although all electrocyclic reactions are allowed both thermally and photochemically providing the rotation is right, the steric requirements for con- or disrotatory cyclization or ring opening may make one or both modes impossible.

Small rings are opened by electrocyclic reactions

Ring strain is important in preventing a reaction that would otherwise change your view of a lot of the chemistry you know. Allyl cations are conjugated systems containing 2$\pi$ electrons, so if you knew no other chemistry than what is in this chapter you might expect them to cyclize via disrotatory electrocyclic ring closure. The product would be a cyclopropyl cation.

In fact, it is the cyclopropyl cations that undergo this reaction (very readily indeed—cyclopropyl cations are virtually unobservable) because ring strain encourages them to undergo electrocyclic ring opening to give allyl cations. The instability of cyclopropyl cations means that, even as they start to form as intermediates, they spring open to give allyl cation-derived products. Try nucleophilic substitution on a cyclopropane ring and this happens.
Electrocyclic ring opening of one type of three-membered ring tells us about the stereochemistry of the process. Many aziridines are stable compounds, but those bearing electron-withdrawing groups are unstable with respect to electrocyclic ring opening. The products are azomethine ylids and can be trapped by $[3 + 2]$ cycloaddition reactions with dipolarophiles.

Because the cycloaddition is stereospecific (suprafacial on both components), the stereochemistry of the products can tell us the stereochemistry of the intermediate ylid, and confirms that the ring opening is conrotatory (the ylid is a $4\pi$ electron system).

The synthesis of a cockroach pheromone using pericyclic reactions

We finish this pair of chapters about pericyclic reactions with a synthesis whose simplicity is outclassed only by its elegance. Periplanone B is a remarkable bis-epoxide that functions as the sex pheromone of the American cockroach. Insect sex pheromones often have economic importance because they can form the key to remarkably effective traps for insect pests.

In 1984, Schreiber published a synthesis of the pheromone in which the majority of steps involve pericyclic reactions. Make sure you understand each one as it appears—re-read the appropriate part of Chapter 34 or this chapter if you have any problems. The first step is a photochemical $[2 + 2]$ cycloaddition. You could not have predicted the regiochemistry, but it is typical of the cycloaddition of allenes with unsaturated ketones.

The product is a mixture of diastereoisomers because of the chiral centre already in the molecule (ringed in green), but it is, of course, fully stereospecific for the two new orange chiral centres in the four-membered ring. The next step adds vinylmagnesium bromide to the ketone—again a mixture of diastereoisomers results.

All the carbon atoms in the 12-membered ring are now present, and they are sorted out by the two steps that follow. The first is a Cope rearrangement: a $[3,3]$-sigmatropic rearrangement, accelerated as we have described (p. 914) by the presence of an alkoxide substituent.
The six-membered ring has expanded to a ten-membered ring. Now for a second ring-expansion step—heating the compound to 175 °C makes it undergo electrocyclic ring opening of the four-membered ring, giving the 12-membered ring we want. Or rather not quite—the new double bond in the ring is formed as a mixture of cis and trans isomers, but irradiation isomerizes the less stable cis to the more stable trans double bond.

The remaining steps in the synthesis involve the insertion of another Z alkene and two epoxides. Pericyclic reactions are particularly valuable in the synthesis and manipulation of rings.

We must now take our leave of this trio of pericyclic reactions and move on to two reaction classes that have appeared frequently in these two chapters, but that also involve mechanisms other than pericyclic ones and deserve a chapter of their own: rearrangements and fragmentations.

The last two chapters introduced pericyclic reactions, and the next one will cover reactions of radicals. Together with the ionic reactions which have been the subject of most of this book, these three classes cover all organic mechanisms. But before we move on to consider radicals, we need to fill a gap in our coverage of ionic reactions. You have met the most important types of ionic reactions—additions, substitutions, and eliminations. But two remain and they are closely related. In rearrangements the molecule changes its carbon skeleton and in fragmentations the carbon skeleton splits into pieces. We lead up to these types of reaction by looking at a phenomenon known as participation.

Neighbouring groups can accelerate substitution reactions

Compare the rates of the following substitution reactions. Each is a substitution of the leaving group (OTs or Cl) by solvent, known as a solvolysis.

A solvolysis was defined in Chapter 15 as ‘a reaction in which the solvent is also the nucleophile’.
Nearby groups can evidently increase the rate of substitution reactions significantly. Now, you may be thinking back to Chapter 15 and saying ‘yes, yes, we know that’—when we were discussing the mechanisms of substitution reactions we pointed out that a cation-stabilizing group at the reaction centre makes SN1 reactions very fast, for example:

\[
\begin{align*}
\text{PhS-Cl} & \text{ reacts with water 600 times faster than} \\
\text{Ph-OTs} & \text{ reacts with CF}_3\text{CO}_2\text{H 3000 times faster than} \\
\text{PhCl} & \text{ reacts with acetic acid 670 times faster than} \\
\text{Ph-OTs} & \text{ reacts with acetic acid 10}^{11} \text{ times faster than}
\end{align*}
\]

In the four examples above, though, it is not at the reaction centre itself that the functional groups change but at the carbon next to the reaction centre, and we call these groups neighboring groups. The mechanism by which they speed up the reactions is known as neighboring group participation. Compare the reaction of this ether and this sulfide with an alcohol.

In both cases, ionization of the starting material is assisted by the lone pair of an electron-rich functional group. The ether in the first example assists by forming a π bond, the sulfide assists by forming a σ bond in a three-membered ring, and a common feature of all mechanisms involving neighbouring group participation is the formation of a cyclic intermediate.

**Stereochemistry can indicate neighbouring group participation**

How do we know that neighbouring group participation is taking place? Well, the first bit of evidence is the increase in rate. The neighbouring groups become involved only if they can increase the rate of the substitution reaction—otherwise the mechanism will just follow the ordinary SN2 pathway. But more important information comes from reactions where stereochemistry is involved, and one of these is the last of the four examples at the start of the chapter. Here it is again in more detail. Not only does the first of these reactions go faster than the second—itits stereochemical course is different too.

Although one starting material has *syn* and the other *anti* stereochemistry, the products have the same (*anti*) stereochemistry one substitution goes with retention and one goes with
inversion. Again, neighbouring group participation is the reason. To explain this, we should first draw the six-membered rings in their real conformation. For the anti compound, both substituents can be equatorial. However, not much can happen in this conformation—but, if we allow the ring to flip, you can see immediately that the acetate substituent is ideally placed to participate in the departure of the tosylate group.

\[
\begin{align*}
\text{AcO} & \quad \text{OTs} \\
\text{both substituents} & \quad \text{equatorial} \\
\text{ring flip} & \\
\text{both substituents} & \quad \text{axial} \\
\text{symmetrical intermediate} & \\
\end{align*}
\]

What results is an entirely symmetrical intermediate—the positive charge on one of the oxygens is, of course, delocalized over both of them. The intramolecular S\textsubscript{N}2 reaction takes place with inversion, as required by the orbitals, so now the junction of the two rings is cis.

The next step is attack of acetic acid on the intermediate. This is another S\textsubscript{N}2 reaction, which also proceeds with inversion and gives back a trans product.

\[
\begin{align*}
\text{HOAc} & \quad \text{AcO} \\
\text{ring flip} & \\
\text{AcO} & \quad \text{AcO} \\
\text{symmetrical intermediate} & \\
\end{align*}
\]

Overall, we have retention of stereochemistry. As you know, S\textsubscript{N}2 reactions go with inversion and S\textsubscript{N}1 reactions with loss of stereochemical information, so this result is possible only if we have two sequential S\textsubscript{N}2 reactions taking place—in other words neighbouring group participation.

Why, then, does the other diastereoisomer react with inversion of stereochemistry? Well, try drawing the mechanism for intramolecular displacement of the tosyl group. Whether you put the tosylate or the acetate group equatorial doesn’t matter; there is no way in which the acetate oxygen's lone pair can reach the \(\sigma^*\) orbital of the tosylate C–O bond.

\[
\begin{align*}
\text{OTs} & \quad \text{AcO} \\
\text{ring flip} & \\
\text{AcO} & \quad \text{AcO} \\
\text{neighbouring group participation} & \\
\end{align*}
\]

Neighbouring group participation is impossible, and substitution goes simply by intermolecular displacement of OTs by AcOH. Just one S\textsubscript{N}2 step means overall inversion of configuration, and no participation means a slower reaction.

\[
\begin{align*}
\text{AcO} & \quad \text{HOAc} \\
\text{ring flip} & \\
\text{AcO} & \quad \text{AcO} \\
\text{neighbouring group participation} & \\
\end{align*}
\]

**Retention of configuration is an indication of neighbouring group participation**

Enantiomerically pure (R)-2-bromopropanoic acid reacts with concentrated sodium hydroxide to give (S)-lactic acid. The reaction goes with inversion and is a typical S\textsubscript{N}2 reaction—and a good one too, since the reaction centre is adjacent to a carbonyl group (see Chapter 15). If, on the other hand, the reaction is run using Ag\textsubscript{2}O and a low concentration of sodium hydroxide, (R)-lactic acid is obtained—there is overall retention of stereochemistry.
Nucleophilic substitution reactions that go with retention of stereochemistry are rather rare and mostly go through two successive inversions with neighbouring group participation, like the example you saw in the last section. This time the neighbouring group is carboxylate: the silver oxide is important because it encourages the ionization of the starting material by acting as a halogen-selective Lewis acid. A three-membered ring intermediate forms, which then gets opened by hydroxide in a second SN₂ step.

Why does the carboxylate group participate only at low HO⁻ concentration and in the presence of Ag⁺? You can think of the situation in these two reactions in terms of the factors that favour SN₁ and SN₂ reactions. In the first, we have conditions suited to an SN₂ reaction: a very good nucleophile (HO⁻) and a good leaving group (Br⁻). Improve the leaving group by adding Ag⁺ (Ag⁺ assists Br⁻'s departure much as H⁺ assists the departure of OH⁻ by allowing it to leave as H₂O) and worsen the nucleophile (H₂O instead of HO⁻, of which there is now only a low concentration), and we have the sorts of conditions that would favour an SN₁ reaction. The trouble is, without neighbouring group participation, the cation here would be rather unstable—right next to a carbonyl group. The carboxylate saves the day by participating in the departure of the Br⁻ and forming the lactone. The key thing to remember is that a reaction always goes by the mechanism with the fastest rate.

What sorts of groups can participate?

You’ve already met the most important ones—sulphides, esters, carboxylates. Ethers and amines (you will see some of these shortly) can also assist substitution reactions through neighbouring group participation. The important thing that they have in common is an electron-rich heteroatom with a lone pair that can be used to form the cyclic intermediate. Sulphides are rather better than ethers—this sulhide reacts with water much faster than n-PrCl but the ether reacts with acetic acid four times more slowly than n-PrOSO₂Ar.

The OMe group slows the reaction down just because it is electronegative more than it accelerates it by participation. A more distant OMe group can participate: this 4-MeO alkyl sulphonate reacts with alcohols 4000 times faster than the n-Bu sulphonate.
Again neighbouring group participation is involved, but this time through a five- rather than a three-membered ring. Participation is most commonly through three- and five-membered rings, less often six-membered ones, and very rarely four- or more than seven-membered ones.

![Diagram of five-membered ring intermediate]

**Mustard gas**

Participation of sulfides through three-membered rings was used to gruesome effect in the development of mustard gas during the Second World War. Mustard gas itself owes its toxicity to the neighbouring group participation of sulfur, which accelerates its alkylation reactions.

![Diagram of mustard gas]

**Not all participating groups have lone pairs**

Another of the four examples we started with shows that even the π electrons of a C=C double bond can participate. Retention of stereochemistry in the product (the starting tosylate and product acetate are both anti to the double bond) and the extremely fast reaction (10^{11} times that of the saturated analogue) are tell-tale signs of neighbouring group participation.

![Diagram of reaction with orbitals involved in π participation]

**What is the structure of the intermediate?**

During the 1950s and 1960s, this sort of question provoked a prolonged and acrimonious debate, which we have no intention of stirring up, and all we will do is point out that the intermediate in this reaction is not fully represented by the structure we have here: it is symmetrical and could be represented by two structures with three-membered rings or by a delocalized structure in which two electrons are shared between three atoms. The difference need not concern us.

![Possible structures for the intermediate]

Finally, an example with a neighbouring phenyl group. Participation is suggested by the retention of relative stereochemistry.

![Diagram of reaction with phenyl group]

Again, π electrons are involved, but the reaction is now electrophilic aromatic substitution (Chapter 21) rather like an intramolecular Friedel–Crafts alkylation with a delocalized intermediate often termed a phenonium ion.
More stereochemical consequences of neighbouring group participation

The phenonium ion is symmetrical. The acetic acid can attack either atom in the three-membered ring to give the same product.

The phenonium ion is nonetheless still chiral, since it has an axis (and not a plane or centre) of symmetry, so if we use an enantiomerically pure starting material we get an enantiomerically pure product.

Not so with the other diastereoisomer of this compound! Now, the phenonium ion is symmetrical with a plane of symmetry—it is therefore achiral, and the same whichever enantiomer we start from. Attack on each end of the phenonium ion gives a different enantiomer, so whichever enantiomer of starting material we use we get the same racemic mixture of products. You can compare this reaction with the loss of stereochemical information that occurs during an $S_N1$ reaction of enantiomerically pure compounds. Both reactions pass through an achiral intermediate.

There is a subtlety here that you should not overlook and that makes this study, which was carried out by Cram in 1949, exceedingly elegant. Reactions of both of these diastereoisomers are stereospecific: the relative stereochemistry of the products depends on the relative stereochemistry of the starting materials. Yet, while the absolute stereochemistry of the starting materials is retained in one case (we get a single enantiomer of a single diastereoisomer), it is lost in the other (we get a racemic mixture of both enantiomers of a single diastereoisomer). These are important distinctions, and if you are in any doubt about these terms, re-read Chapters 14 and 33. Donald Cram (1919–2001) of UCLA was awarded the Nobel prize in 1987 jointly with Jean-Marie Lehn (1939–) of Strasbourg and Paris, and Charles Pedersen (a Norwegian born in Korea in 1904) of DuPont for ‘their development and use of molecules with structure-specific interactions of high selectivity’.
The same loss of absolute stereochemical information (but retention of relative stereochemistry) occurs in another reaction that you met at the start of this chapter. We then emphasized two features: the acceleration in rate and the retention of stereochemistry.

\[ \text{anti diastereoisomer} \rightarrow \text{AcOH} \rightarrow \text{anti diastereoisomer} \]

The intermediate oxonium ion is delocalized and achiral. If a single enantiomer of the starting material is used, racemic product is formed through this achiral intermediate. Attack at one carbon atom gives one enantiomer; attack at the other gives the mirror image.

\[ \text{AcOH} \rightarrow \text{(+) the other enantiomer of the anti diastereoisomer} \]

In this case the neighbouring group can be caught in the act—when the rearrangement is carried out in ethanol, the intermediate is trapped by attack at the central carbon atom. It is as though someone switched the light on while the acetate’s fingers were in the biscuit tin. The product is an orthoester and is achiral too. This chemistry should remind you of the formation of acetals, as described in Chapter 11.

\[ \text{anti diastereoisomer} \rightarrow \text{EtOH} \rightarrow \text{51% yield} \]

**Rearrangements occur when a participating group ends up bonded to a different atom**

Because the intermediates in these examples are symmetrical, 50% of the time one substituent ends up moving from one carbon atom to another during the reaction. This is clearer in the following example: the starting material is prepared such that the carbon atom carrying the phenyl group is an unusual isotope—carbon-14. This doesn’t affect the chemistry, but means that the two carbon atoms are easily distinguishable. Reacting the compound with trifluoroacetic acid scrambles the label between the two positions: the intermediate is symmetrical and, in the 50% of reactions with the nucleophile that take place at the labelled carbon atom, the phenyl ends up migrating to the unlabelled carbon atom in a rearrangement reaction.

\[ \text{14C label} \rightarrow \text{RCO2H} \rightarrow \text{unrearranged product} \rightarrow \text{rearranged product} \]

Now, consider this substitution reaction, in which OH replaces Cl but with a change in the molecular structure. The substitution goes with complete rearrangement—the amine ends up attached to a different carbon atom. We can easily see why if we look at the mechanism. The reaction starts off looking like a neighbouring group participation of the sort you are now familiar with (the carbon atoms are numbered for identification).
The intermediate is an aziridinium ion (aziridines are three-membered rings containing nitrogen—the nitrogen analogues of epoxides). The hydroxide ion chooses to attack only the less hindered terminal carbon 1, and a rearrangement results—the amine has migrated from carbon 1 to carbon 2.

We should just pause here for a moment to consider why this rearrangement works. We start with a secondary alkyl chloride that contains a very bad leaving group (Et₂N) and a good one (Cl⁻)—but the good one is hard for HO⁻ to displace because it is at a secondary centre (remember—secondary alkyl halides are slow to react by SN₁ or SN₂). But the NEt₂ can participate to make an aziridinium intermediate—now there is a good leaving group (RNEt₂ without the negative charge) at the primary as well as the secondary carbon, so HO⁻ does a fast SN₂ reaction at the primary carbon.

Another way to look at this reaction is to see that the good internal nucleophile Et₂N will compete successfully for the electrophile with the external nucleophile HO⁻. Intramolecular reactions are usually faster than bimolecular reactions.

The Payne rearrangement

The reaction of an epoxy alcohol in base does not always give the expected product.
Now we do have a reactive, primary electrophilic site, which undergoes an $S_N2$ reaction with the $t$-BuS$^-$ under the conditions of the rearrangement. Notice how the black OH, which started on the carbon labelled 1, has ended up on carbon 2.

**The direction of rearrangement can depend on the nucleophile**

Compare these reactions: you saw the first on p. 938 but the second is new.

In the first reaction, the amine migrates from the primary to the secondary position; in the other from secondary to primary. Both go through very similar aziridinium intermediates, so the difference must be due to the regioselectivity with which this aziridinium ion opens in each case.

The only important difference is the nucleophile used in the reaction. Hydroxide opens the aziridinium at the less hindered end; water opens the aziridinium ion at the more hindered (more substituted) end. Why?

We can think of the aziridinium ion as a compound containing two alternative leaving groups—one from a primary centre and one from a secondary one. Primary centres can take part in fast $S_N2$ reactions, but cannot undergo $S_N1$. Secondary centres can undergo either $S_N1$ or $S_N2$ reactions, but, in general, do neither very well. Now, the rate of an $S_N2$ reaction depends on the nucleophile, so a good nucleophile (like HO$^-$) can do fast $S_N2$ reactions, while a bad one (like H$_2$O) cannot. The fastest reaction HO$^-$ can do then is $S_N2$ at the primary centre (remember: you see only the reaction that goes by the fastest mechanism). Water, on the other hand, takes part only reluctantly in substitution reactions—but this does not matter if they are $S_N1$ reactions because their rates are independent of nucleophile. H$_2$O waits until the leaving group has left of its own accord to give a cation, which rapidly grabs *any* nucleophile—water will do just as well as HO$^-$. This can happen only at the secondary centre because the primary cation is too unstable to form.

All the rearrangements you have met so far occurred during substitution reactions. All happened because reaction *with* rearrangement is faster than reaction *without* rearrangement—in other words, rearrangement occurs because of a kinetic preference for the rearrangement pathway. You could see these reactions as ‘special case’ examples of neighbouring group participation—in both participation and rearrangement the neighbouring group speeds up the
reaction, but in rearrangement reactions the neighbouring group gets rather more than it bargained for, and ends up elsewhere in the molecule. Both proceed through a cyclic transition state or intermediate, and it is simply the way in which that transition state or intermediate collapses that determines whether rearrangement occurs.

Rearrangement can involve migration of alkyl groups

This example is a nucleophilic substitution under conditions (Ag\(^+\), H\(_2\)O) designed to encourage \(S_n1\) reactions (excellent leaving group, poor nucleophile). First of all, this is what does not happen (and indeed without Ag\(^+\) nothing happens at all).

\[
\text{I} \quad \xrightarrow{\text{AgNO}_3, \text{H}_2\text{O}} \quad \text{OH}
\]

Compounds like this, with a \(t\)-butyl group next to the electrophilic centre, are notoriously slow to undergo substitution reactions. They can’t do \(S_n2\), they are too hindered; they can’t do \(S_n1\), the cation you would get is primary. In fact, a rearrangement occurs. One of the methyl groups moves (‘migrates’) from carbon 2 to carbon 1, the new OH group taking its place at carbon 2.

How has this happened? Well, firstly, our principle (p. 934) tells us that it has happened because \(S_n1\) and \(S_n2\) are both so slow that this new rearrangement mechanism is faster than either. Adding Ag\(^+\) makes \(\text{I}^-\) desperate to leave, but unassisted this would mean the formation of a primary carbocation. The molecule does the only thing it can to stop this happening and uses the electrons in an adjacent C–C bond to assist the departure of \(\text{I}^-\). Having participated, the methyl group continues to migrate to carbon 1 because by doing so it allows the formation of a stable tertiary carbocation, which then captures water in a step reminiscent of the second half of an \(S_n1\) reaction. Note the cyclic transition state where the migrating group is partially bonded to two carbon atoms.

In the migration step we used a slightly unusually S-shaped curly arrow to represent the movement of a group (Me) along a bond taking its bonding electrons with it. We shall use this type of arrow when a group migrates from one atom to another during a rearrangement.

Carbocations readily rearrange

In Chapter 15 we showed you that it is possible to run the NMR spectra of carbocations by using a polar but non-nucleophilic solvent such as liquid SO\(_2\) or SOCl\(_2\). Treating an alkyl halide \(RX\) with the powerful Lewis acid Sb\(_2\)F\(_5\) under these conditions gives a solution of carbocation: the carbocation reacts neither with solvent nor the Sb\(_2\)F\(_5\)\(^-\) counterion because neither is nucleophilic. We know, for example, that the chemical shifts in both the \(\delta^1^C\) and \(\delta^1^H\) NMR spectra of the \(t\)-butyl cation are very large, particularly the \(\delta^1^C\) shift at the positively charged centre.
NMR can be used to follow the course of rearrangement reactions involving carbocations too. We can illustrate this with an experiment that tries to make the neopentyl cation by the substitution reaction you have just seen. This time the starting material and solvent are slightly different, but the outcome is nonetheless most revealing. Dissolving neopentyl tosylate in fluorosulfonic acid (a strong, non-nucleophilic acid) at –77°C gives a 77% yield of a cation whose spectrum is shown below. Assigning the peaks is not hard once you know that the same spectrum is obtained when 2,2-dimethyl-2-butanol is dissolved in fluorosulfonic acid with SbF₅ added.

Clearly, the spectrum is the tertiary 2-methylbutyl cation and the neopentyl cation never saw the light of day. The reaction is the same rearrangement that you saw in the substitution reaction of neopentyl iodide, but here the rate of rearrangement can be measured and it is extremely fast. Neopentyl tosylate reacts to form a cation under these conditions about 10⁴ times as fast as ethyl tosylate, even though both tosylates are primary. This massive rate difference shows that if migration of an alkyl group can allow rearrangement to a more stable carbocation, it will happen, and happen rapidly.

Primary cations can never be observed by NMR—they are too unstable. But secondary cations can, provided the temperature is kept low enough. sec-Butyl chloride in SO₂ClF at –78°C gives a stable, observable cation. But, as the cation is warmed up, it rearranges to the t-butyl cation. Now this rearrangement truly is a carbocation rearrangement: the starting material is an observable carbocation and so is the product, and we should just look at the mechanism in a little more detail.

With rearrangements like this it is best to number the C atoms so you can see clearly what moves where. If we do this, we see that the methyl group we have labelled 4 and the H on C₃ have changed places. (Note that C₃ starts off as a CH₂ group and ends up as CH₃.)

Top tip for rearrangements
Number the carbon atoms in the starting material and product before you try to work out the mechanism.

Using the sort of arrows we introduced on p. 940, we can draw a mechanism for this in which first the Me migrates, and then the hydride. We say hydride migration rather than hydrogen (or proton) because the H atom migrates with its pair of electrons.

As these rearrangements are a new type of reaction, we should just spend a moment looking at the molecular orbitals that are involved. For the first step, migration of the methyl group,
the LUMO must clearly be the empty p orbital of the cation, and the HOMO is the C–C σ bond, which is about to break.

The methyl group can slide smoothly from one orbital to another—there are bonding interactions all the way. The next step, migration of H, is just the same—except that the HOMO is now a C–H σ bond. The methyl migration is thermodynamically unfavourable as it transforms a secondary cation into an unstable primary cation but the hydride migration puts that right as it gives a stable tertiary cation. The whole reaction is under thermodynamic control.

**Wagner–Meerwein rearrangements**

Carbocation rearrangements involving migration of H or alkyl groups don’t just happen in NMR machines. They happen during normal reactions too. For example, acid-catalysed dehydration of the natural product camphenilol gives the alkene santene (a key component of the fragrance of sandalwood oil) in a reaction involving migration of a methyl group.

The mechanism shows why the rearrangement happens: the first-formed cation cannot eliminate H⁺ in an E1 reaction because loss of the only available proton would give a very strained bridgehead alkene (make a model and see!).

However, migration of a methyl group both stabilizes the cation—it becomes tertiary instead of secondary—and allows E1 elimination of H⁺ to take place to give a stable alkene.

The migration of an alkyl group to a cationic centre is known as a Wagner–Meerwein rearrangement or Wagner–Meerwein shift, and this migration is, of course, a synthetic manifestation of the rearrangement we have just been looking at in NMR spectra. Wagner–Meerwein shifts have been studied extensively in the class of natural products to which both of these natural products belong—terpenes. For the moment, though, we will just illustrate this type of reaction with one more example—another acid-catalysed dehydration, of isoborneol to give camphene.
This one seems much more complicated—but, in fact, only one alkyl migration is involved. To see what has happened, remember the ‘top tip’—number the carbons. You can number the starting material any way you choose—we’ve started with the gem-dimethyl group because it will be easy to spot in the product. The numbers just follow round the ring, with C8 being the methyl group attached to C5.

Now for the hard bit—we need to work out which carbon in the starting material becomes which carbon in the product. The best thing is just to have a go—mistakes will soon become obvious and you can always try again.

- Use the substituents to help you—some will have changed, but most will be the same or similar, for example C1 is still easy to spot as the carbon carrying the dimethyl group.
- Use connectivity to help you—again, a C–C bond or two may have broken or formed, but most of the C–C bonds in the starting material will be there in the product. C1 and C2 will probably still be next door to one another—C2 was a bridgehead carbon in the starting material, and there is a bridgehead C attached to C1 in the product; assume that’s C2.
- C3 and C4 were unsubstituted carbons in the starting material, and are identifiable in the product too. The other easily spotted atom is C7—an unsubstituted C attached to C2.
- C5, C6, and C8 are harder. We can assume that C8 is the =CH₂ carbon—it was a methyl group but perhaps has become involved in an elimination. C5 was attached to C1, C4, C6, and C8: one of the remaining carbons is attached to C1 and C8, so that seems more likely to be C5, which leaves C6 as the bridgehead, attached as before to C7 and C5.

Now we have the whole picture and we can assess what has happened in the reaction—which old bonds have broken and which new bonds have formed.

Numbering the atoms this way identifies the likely point of rearrangement—the only bond broken is between C4 and C5. Instead we have a new one between C4 and C6: C4 appears to have migrated from C5 to C6.

Now for the mechanism. The first step will, of course, be loss of water to generate a secondary cation at C6. The cation is next to a quaternary centre, and migration of any of three bonds could generate a more stable tertiary carbocation. But we know that the new bond in the product is between C4 and C6, so let’s migrate carbon 4. Manipulating the diagrams a bit turns up a structure remarkably similar to our product, and all we need to do is lose a proton from C8.
Although migration of an alkyl group that forms part of a ring leads to much more significant changes in structure than simple migration of a methyl group, the reason why it happens is still just the same.

- **Alkyl migrations occur in order to make a carbocation more stable.**

### Ring expansion means rearrangement

‘More stable’ usually means ‘more substituted’, but cations can also be made more stable if they become less strained. So, for example, four-membered rings adjacent to cations readily rearrange to five-membered rings in order to relieve ring strain.

This time the cation is formed by protonation of an alkene, not departure of a leaving group, but writing a mechanism should now be a straightforward matter to you.

Although the rearrangement step transforms a stable tertiary cation into a less stable secondary cation, relief of strain in expansion from a four- to a five-membered ring makes the alkyl migration favourable. A synthesis of the natural product α-caryophyllene alcohol makes use of a similar ring expansion. Notice the photochemical [2 + 2] cycloaddition (Chapter 34) in the synthesis of the starting material.

Rearrangement of this tertiary alcohol in acid gives the target natural product. The four-membered ring has certainly disappeared but it may not be obvious at first what has taken its place.

As usual, numbering the atoms makes clear what has happened: carbon 7 has migrated from carbon 6 to carbon 5. Loss of water gives a tertiary carbocation that undergoes rearrangement to a secondary carbocation with expansion of a four- to a five-membered ring.
Carbocation rearrangements: blessing or curse?

Well, that depends. You have now seen a few useful carbocation rearrangements that give single products in high yield. But you have also met at least one reaction that cannot be done because of carbocation rearrangements: as we mentioned in Chapter 15, Friedel–Crafts alkylation using primary alkyl halides leads to products derived from rearranged cations. The alkylation in the margin illustrates the problems of trying to use carbocation rearrangements to make single products in high yield. We can give three guidelines to spotting this type of reaction.

1. The rearrangement must be fast so that other reactions do not compete.
2. The product cation must be sufficiently more stable than the starting one so that the rearrangement happens in high yield.
3. Subsequent trapping of the product cation must be reliable: cations are high-energy intermediates, and are therefore unselective about how they react.

A reaction is no good if the cation reacts in more than one way—it may react with a nucleophile, eliminate, or undergo further rearrangement—but it must do only one of these! For the rest of the chapter, we will address only reactions that, unlike this Friedel–Crafts reaction, follow these guidelines. The reactions we will talk about all happen in good yield.

The pinacol rearrangement

When the 1,2-diol pinacol is treated with acid, a rearrangement takes place.

Whenever you see a rearrangement, especially in acid, you should now think ‘carbocation’. Here, protonation of one of the hydroxyl groups allows it to leave as water, giving the carbocation.

You now know that carbocations rearrange by alkyl shifts to get as stable as they can be—but this carbocation is already tertiary, and there is no ring strain, so why should it rearrange? Well, here we have another source of electrons to stabilize the carbocation: lone pairs on an oxygen atom. We pointed out early in the chapter that oxygen is very good at stabilizing a positive charge on an adjacent atom, and somewhat less good at stabilizing a positive charge two atoms away. By rearranging, the first-formed carbocation gets the positive charge into a position where the oxygen can stabilize it, and loss of a proton from oxygen then gives a stable ketone.
You can view the pinacol as a rearrangement with a ‘push’ and a ‘pull’. The carbocation left by the departure of water ‘pulls’ the migrating group across at the same time as the oxygen’s lone pair ‘pushes’ it. A particularly valuable type of pinacol rearrangement forms spirocyclic ring systems. You may find this one harder to follow, although the mechanism is identical with that of the last example. Our ‘top tip’ of numbering the atoms should help you to see what has happened: atom 2 has migrated from atom 1 to atom 6.

When drawing the mechanism it doesn’t matter which hydroxyl group you protonate or which adjacent C–C bond migrates—they are all the same. One five-membered ring expands to a six-membered ring but the reason this reaction happens is the formation of a carbonyl group, as in all pinacol rearrangements.

Epoxides rearrange with Lewis acids in a pinacol fashion

The intermediate cation in a pinacol rearrangement can equally well be formed from an epoxide, and treating epoxides with acid, including Lewis acids such as MgBr₂, promotes the same type of reaction.

Rearrangement of epoxides with magnesium salts means that opening epoxides with Grignard reagents can give surprising results.

The alkyllithium reaction is quite straightforward as long as the alkyllithium is free of lithium salts. A clue to what has happened with the Grignard reagents comes from the fact that treating this epoxide with just MgBr₂ (not RMgBr) gives an aldehyde.

With a Grignard reagent, rearrangement occurs faster than addition to the epoxide, and then the Grignard reagent adds to the aldehyde.
**Some pinacol rearrangements have a choice of migrating group**

With these symmetrical diols and epoxides, it does not matter which hydroxyl group is protonated and leaves, nor which end the epoxide opens, nor which group migrates. When an unsymmetrical diol or epoxide rearranges, it is important which way the reaction goes. Usually, the reaction leaves behind the more stable cation. So, for example, this unsymmetrical diol gives the ring-expanded ketone, a starting material for the synthesis of analogues of the drug methadone.

This product is formed because the green OH group leaves more readily than the black as the carbocation stabilized by two phenyl groups forms more readily than the carbocation stabilized by two alkyl groups. The migration step which follows has no choice: both alkyl groups on the black alcohol are the same.

Most unsymmetrical diols or epoxides give mixtures of products on rearrangement. The problem is that there is a choice of two leaving groups and two alternative rearrangement directions, and only for certain substitution patterns is the choice clear-cut.

**Semipinacol rearrangements are pinacol reactions with no choice about which way to go**

For some work on perfumery compounds, this seven-membered cyclic ketone was needed. A reasonable starting material to use is the diol shown because it can be made in two steps from the natural product isonopinone.

The reaction needed for the last stage is a pinacol rearrangement—the primary hydroxyl group needs persuading to leave as the ring expands. The problem is, of course, that the tertiary hydroxyl group is much more likely to leave since it leaves behind a more stable carbocation.

The solution to this problem is to force the primary hydroxyl group to be the leaving group by making it into a tosylate. The primary hydroxyl group reacts more rapidly with TsCl than the tertiary one because it is less hindered. A weak base is now all that is needed to make the compound rearrange in what is known as a semipinacol rearrangement.
Semipinacol rearrangements are rearrangements in which a hydroxyl group provides the electrons to ‘push’ the migrating group across, but the ‘pull’ comes from the departure of leaving groups other than water—tosylate in this example, but typically also halide or nitrogen (N₂). Since tosylation occurs at the less hindered hydroxyl group of a diol, not only can semipinacol rearrangements be more regioselective than pinacol rearrangements, but their regioselectivity may be in the opposite direction.

Corey exploited this in a synthesis of the natural product longifolene. He needed to persuade an easily made 6,6-fused ring system to undergo rearrangement to a ring-expanded ketone. Again, a normal acid-catalysed pinacol rearrangement is no good—the tertiary, allylic hydroxyl group is much more likely to ionize, and the acid-sensitive protecting group would be hydrolysed too. Tosylation of the secondary alcohol in the presence of the tertiary is possible, and semipinacol rearrangement gives the required ketone.

The leaving group need not be tosylate: in the following example, part of a synthesis of bergamotene (a component of valerian root oil and the aroma of Earl Grey tea), a 2-iodo alcohol rearranges.

**Semipinacol rearrangements of diazonium salts**

You saw in Chapter 21 how aromatic amines can be converted to diazonium salts by treatment with acidic sodium nitrite.

[Treating 2-halo alcohols with base is, of course, a good way to make epoxides. Using AgNO₃ to improve iodide’s leaving ability without increasing the nucleophilicity of the hydroxyl group favours rearrangement at the expense of epoxide formation. There would certainly be a danger of epoxide formation in strong base.](#)

[It might be an idea to review pp. 520–523 of Chapter 22 to be sure you understand the mechanism of this reaction.](#)
Aryldiazonium salts are stable but alkyldiazonium salts are not: nitrogen gas is the world’s best leaving group, and, when it goes it leaves behind a carbocation.

\[
\text{R} = \text{alkyl} \quad \begin{array}{c}
\text{NaNO}_2, \text{HCl} \\
\begin{array}{c}
\text{R} \\
\cdot \text{N} \\
\cdot \text{N} \\
\cdot \text{Cl}
\end{array}
\end{array} \quad R^\ominus \quad \text{further reactions}
\]

One of the ‘further reactions’ this carbocation can undergo is rearrangement. If the starting amine is a 2-amino alcohol, the cation can be stabilized by a semipinacol rearrangement.

While alkyldiazonium salts are unstable, their conjugate bases, diazoalkanes, are stable enough to be prepared and are nucleophilic towards carbonyl compounds. Diazoalkanes are neutral compounds having one fewer proton than diazonium salts, and are delocalized structures with a central sp nitrogen atom.

When diazomethane (a compound we will investigate in more detail in Chapter 38) adds to a ketone, the product undergoes a ring expansion by rearrangement of the same type of intermediate.

The problem with reactions like this is that both the starting material and product are ketones, so they work cleanly only if the starting material is more reactive than the product. Cyclohexanone is more reactive as an electrophile than either cyclopentanone or cycloheptanone, so it ring expands cleanly to cycloheptanone. But expansion of cyclopentanone to cyclohexanone is messy and gives a mixture of products.

**The dienone-phenol rearrangement**

The female sex hormone oestrone is the metabolic product of another hormone, progesterone, itself made in the body from cholesterol.

Oestrone lacks one of progesterone’s methyl groups, probably removed in the body as CO₂ after oxidation. In 1946, Carl Djerassi, a man whose work led directly to the invention of the contraceptive pill, showed that another derivative of cholesterol could be rearranged to the oestrone analogue 1-methyloestradiol—notice how the methyl group has this time migrated to an adjacent carbon atom. At the same time, the dienone has become a phenol.
This type of rearrangement is known helpfully as a dienone-phenol rearrangement, and we can consider it quite simply as a type of reverse pinacol rearrangement. Pinacol and semipinacol rearrangements are driven by the formation of a carbonyl group. The rearranged cation is stabilized by being next to oxygen and it can rapidly lose H\(^+\) to give a carbonyl compound. In the key step of a dienone-phenol rearrangement, a protonated carbonyl compound rearranges to a tertiary carbocation. The reaction is driven from dienone to phenol because the product cation can rapidly undergo elimination of H\(^+\) to become aromatic.

The benzilic acid rearrangement

You have seen rearrangements in which carbonyl groups form at the migration origin: the migrating group in the pinacol and semipinacol rearrangements is ‘pushed’ by the oxygen’s lone pair as it forms the new carbonyl group. You have also seen carbonyl groups being destroyed at the migration terminus: the migrating group in the dienone-phenol rearrangement is ‘pulled’ towards the protonated carbonyl group. The first rearrangement reaction ever to be described has both of these at once.

In 1838, Justus von Liebig found that treating ‘benzil’ (1,2-diphenylethan-1,2-dione) with hydroxide gave, after acid quench, 2-hydroxy-2,2-diphenylacetic acid, which he called ‘benzilic acid’. The mechanism of this benzilic acid rearrangement starts with attack of hydroxide on one of the carbonyl groups. The tetrahedral intermediate can collapse in a reaction reminiscent of a semipinacol rearrangement.

The Favorskii rearrangement

We hope you have appreciated the smooth mechanistic progression so far in this chapter, from Wagner–Meerwein to pinacol and semipinacol through dienone-phenol to benzilic acid.
Our aim is to help you gain an overall view of the types of rearrangements that take place (and why) and not to present you with lots of disconnected facts. It is at this point, however, that our mechanistic journey takes a hairpin bend. The bend comes as a surprise because when we show you the next rearrangement, the Favorskii, you would be forgiven for thinking that surely it’s just a variant of the benzilic acid rearrangement?

Well, this is what chemists thought until 1944, when some American chemists found that two isomeric α-chloro ketones gave exactly the same product on treatment with methoxide. They suggested that both reactions went through the same intermediate.

There is also a pericyclic mechanism for the ring-closure step. The enolate simply loses chloride to give an ‘oxyallyl cation’—a dipolar species with an oxyanion and a delocalized allylic cation. This species can cyclize in a two-electron disrotatory electrocyclic reaction (Chapter 35) to give the same cyclopropanone.

Cyclopropanones are very reactive towards nucleophiles, and the tetrahedral intermediate arising from the attack of methoxide springs open to give the ester product. The more stable carbanion leaves: although the carbanion is not actually formed as a free species, there must be considerable negative charge at the carbon atom as the three-membered ring opens. Here the benzyl group is the better leaving group.
Favorskii rearrangement of cyclic 2-bromoketones leads to ring contraction and this has become one of the most fruitful uses of the rearrangement in synthesis. Bromination of cyclohexanone (Chapter 20) and treatment with methoxide gives the methyl ester of cyclopentane carboxylic acid in good yield.

Enolization occurs on the side of the ketone away from the bromine atom and the enolate cyclizes as before but the cyclopropanone intermediate is symmetrical so that the product is the same whichever C–C bond breaks after nucleophilic attack by the methoxide ion.

Cubane from a Favorskii rearrangement

In 1964, two American chemists synthesized for the first time a remarkable molecule, cubane. Two of the key steps were Favorskii rearrangements, which allowed the chemists to contract five-membered rings to four-membered rings. Here is one of them. Two more steps decarboxylate the product to give cubane itself.

The overall consequence of the Favorskii rearrangement is that an alkyl group is transferred from one side of a carbonyl group to the other. This means that it can be used to build up heavily branched esters and carboxylic acids—the sort that are hard to make by alkylation (Chapter 25) because of the problems of hindered enolates and unreactive secondary alkyl halides. Heavily substituted acids, where CO₂H is attached to a tertiary carbon atom, would be hard to make by any other method.

The Favorskii rearrangement is also a key step in the synthesis of the powerful obstetric painkiller pethidine. But try writing a mechanism for this last reaction and you run into a problem—there are no acidic protons so the ketone cannot be enolized! Yet the Favorskii rearrangement still works. Despite our warnings against confusing the mechanisms of the Favorskii and benzilic acid rearrangements, the Favorskii rearrangement may, in fact, follow a benzilic-type rearrangement mechanism, if there are no acidic hydrogens available.
Migration to oxygen: the Baeyer–Villiger reaction

In 1899, two Germans, A. Baeyer and V. Villiger, found that treating a ketone with a peracid (RCO₂H) can produce an ester. An oxygen atom is ‘inserted’ next to the carbonyl group. You saw a similar ‘insertion’ reaction earlier in the chapter, and the mechanism here is not dissimilar.

Both peracids and diazomethane contain a nucleophilic centre that carries a good leaving group, and addition of peracid to the carbonyl group gives a structure that should remind you of a semipinacol intermediate with one of the carbon atoms replaced by oxygen.

Carboxylates are not such good leaving groups as nitrogen, but the oxygen–oxygen single bond is very weak. Once the peracid has added, loss of carboxylate is concerted with a rearrangement driven by formation of a carbonyl group.

Baeyer–Villiger reactions are among the most useful of all rearrangement reactions, and the most common reagent is m-CPBA (meta-chloroperbenzoic acid) because it is commercially available.

Which group migrates? (I): the facts

A question we have deliberately avoided up to this point is this: when there is a competition between two migrating groups, which group migrates? This question arises in pinacol, semipinacol, and dienone-phenol rearrangements and in Baeyer–Villiger reactions (in the benzilic acid and Favorskii rearrangements, there is no choice) and the awkward fact is that the answer is different in each case! However, let’s start with the Baeyer–Villiger reaction because here the question is always valid except when the ketone being oxidized is symmetrical. Here are some examples; you can probably begin to draw up guidelines for yourself.
The order, with tert-alkyl the best at migrating, then sec-alkyl closely followed by Ph, then Et, then Me, very roughly follows the order in which the groups are able to stabilize a positive charge. Primary groups are much more reluctant to undergo migration than secondary ones or aryl groups, and this makes regioselective Baeyer–Villiger reactions possible.

The Baeyer–Villiger reaction has solved a regioselectivity problem here. L-tyrosine, a relatively cheap amino acid, can be converted to the important drug L-dopa provided it can be hydroxylated ortho to the OH group. This is where electrophilic substitutions of the phenol take place, but electrophilic substitutions with ‘HO⁺’ are not possible. However, after a Friedel–Crafts acylation, the acyl group can be converted to hydroxyl by the Baeyer–Villiger reaction and hydrolysis. The Baeyer–Villiger reaction means that MeCO⁺ can be used as a synthetic equivalent for ‘HO⁺’. Note the unusual use of the less reactive H₂O₂ as oxidizing agent in this reaction. This is possible only when the migrating group is an electron-rich aromatic ring; these reactions are sometimes called Dakin reactions.

**Unsaturated ketones may epoxidize or undergo Baeyer–Villiger rearrangement**

Peracids may epoxidize alkenes faster than ketones take part in Baeyer–Villiger reactions, so unsaturated ketones are not often good substrates for Baeyer–Villiger reactions. The balance is rather delicate. The two factors that matter are: how electrophilic is the ketone and how nucleophilic is the alkene? You might like to consider why this reaction does work, and why the C=O double bond here is particularly unreactive.

Small-ring ketones can relieve ring strain by undergoing Baeyer–Villiger reactions—this cyclobutanone (an intermediate in a synthesis of the perfumery compound cis-jasmone) is
made by a ketene [2 + 2] cycloaddition, and is so reactive that it needs only H₂O₂ to rearrange. Unlike CF₃CO₂H or m-CPBA, H₂O₂ will not epoxidize double bonds unless they are electron-deficient (see Chapter 22).

One point to note about both of the last two reactions is that the insertion of oxygen goes with retention of stereochemistry. You may think this is unsurprising in a cyclic system like this and, indeed, the first of the two cannot possibly go with inversion. However, this is a general feature of Baeyer–Villiger reactions, even when inversion would give a more stable product.

Even when you might imagine that racemization would occur, as in this benzylic ketone, retention is the rule.

By looking at the orbitals involved, you can see why this must be so. The sp³ orbital of the migrating carbon just slips from one orbital to the next with the minimum amount of structural reorganization. The large lobe of the sp³ orbital is used so the new bond forms to the same face of the migrating group as the old one, and stereochemistry is retained.

The orbital interactions in all 1,2-migrations are similar, and the migrating group retains its stereochemistry in these too. In the more familiar S₅2 reaction, inversion occurs because the antibonding σ* orbital rather than the bonding σ orbital is used. In the S₅2 reaction, carbon undergoes nucleophilic attack with inversion; in rearrangements the migrating carbon atom undergoes electrophilic attack with retention of configuration.

- In 1,2-migrations, the migrating group retains its stereochemistry.

Which group migrates? (II): the reasons

Why does the more substituted group migrate in the Baeyer–Villiger reaction? The transition state has a positive charge spread out over the molecule as the carboxylate leaves as an anion. If the migrating group can take some responsibility for the positive charge the transition state will be more stable. The more stable the charge, the faster the rearrangement.
When a benzene ring migrates, π participation is involved as the benzene ring acts as a nucleophile and the positive charge can be spread out even further. Note that the Ph is stabilizing the charge here in the way that it stabilizes the intermediate in an electrophilic aromatic substitution reaction—like a pentadienyl cation rather than like a benzylic cation. What was a transition state in alkyl migration becomes an intermediate in phenyl migration.

The situation in other rearrangements is much more complicated—and indeed more complicated than many textbooks would have you believe. We shall look just briefly at the dienone-phenol rearrangement again, this time considering reactions in which there is competition between two different migrating groups. As in the Baeyer–Villiger reaction, the transition state is cationic, so you would expect cation-stabilizing groups to migrate more readily. This appears to be true for Ph versus Me, but is most definitely not true for Ph versus CO₂Et. The cation destabilizing group CO₂Et migrates even though Ph is much better at stabilizing a positive charge!

The reason is that CO₂Et is so cation destabilizing that it prefers to migrate rather than be left behind next door to a cation. In this case, then, it is the cation-stabilizing ability of the group that does not migrate that matters most.

**Which group migrates? (III): stereochemistry matters too**

Selectivity in rearrangement reactions is affected by the electronic nature of both the group that migrates and the group that is left behind. But there is more! Stereochemistry is important too. The outcome of diazotization and semipinacol rearrangement (Tiffeneau–Demjanov
rearrangement, p. 949) of this amino-alcohol depends entirely on the diastereoisomer you start with. There are four diastereoisomers, and we have drawn each one in the only conformation it can reasonably adopt, with the t-butyl group equatorial.

In all of these reactions, the OH group provides the electronic ‘push’. In the first two reactions, the ring contracts by an alkyl migration from the secondary alcohol, while in the third it is H that migrates from the same position.

The only difference between the compounds is stereochemistry and, if we look at the orbitals involved in the reactions, we can see why this is so important. As the $\text{N}_2$ leaving group departs, electrons in the bond to the migrating group have to flow into the C–N $\sigma^*$ orbital—we discussed this on p. 949. But what we didn’t talk about then was the fact that best overlap between these two orbitals (\(\sigma\) and $\sigma^*$) occurs if they are anti-periplanar to one another—just as in an E2 elimination reaction.

For the first two compounds, with the –$\text{N}_2^+$ group equatorial, the group best placed to migrate is the alkyl group that forms the ring; for the third reaction, there is a hydrogen atom anti-periplanar to the leaving group, so H migrates.

The fourth reaction has, rather than a group that might migrate, the hydroxyl group ideally placed to displace $\text{N}_2$ and form an epoxide.
The requirement for the migrating group to be anti-periplanar to the leaving group is quite general in rearrangement reactions. The reason we haven’t noticed its effect before is that most of the compounds we have considered have not been conformationally constrained in the way that these are. Free rotation means that the right geometry for rearrangement is always obtainable—stereochemistry is not a factor in the Baeyer–Villiger reaction, for example. We will come back to some more aspects of stereochemical control later in the chapter, when we deal with fragmentation reactions. Before then, we will consider one last rearrangement reaction, in which stereochemistry again plays an important controlling role.

The Beckmann rearrangement

The industrial manufacture of nylon relies on the alkaline polymerization of a cyclic amide known trivially as caprolactam. Caprolactam can be produced by the action of sulfuric acid on the oxime of cyclohexanone in a rearrangement known as the Beckmann rearrangement.

The mechanism of the Beckmann rearrangement follows the same pattern as a pinacol or Baeyer–Villiger reaction: acid converts the oxime OH into a leaving group, and an alkyl group migrates to nitrogen as water departs. The product cation is then trapped by water to give an amide.

This rearrangement is not confined to cyclic oximes, and other ways of converting OH to a leaving group also work, such as PCl₅, SOCl₂, and other acyl or sulfonyl chlorides. In an acyclic Beckmann rearrangement, the product cation is better represented as this nitrilium ion. When we write the mechanism we can then involve the nitrogen’s lone pair to ‘push’ the migrating group back on to N.

Which group migrates in the Beckmann rearrangement?

In the Beckmann rearrangement of unsymmetrical ketones there are two groups that could migrate. There are also two possible geometrical isomers of an unsymmetrical oxime: C=N double bonds can exhibit cis/trans isomerism just as C=C double bonds can. When mixtures of geometrical isomers of oximes are rearranged, mixtures of products result, but the ratio of products mirrors exactly the ratio of geometrical isomers in the starting materials—the group that has migrated is in each case the group trans to the OH in the starting material.
We have already touched on the idea that, for migration to occur, a migrating group has to be able to interact with the \( \sigma^* \) of the bond to the leaving group, and this is the reason for the specificity here. In the example a couple of pages back the stereospecificity of the reaction was due to the starting material being constrained in a conformationally rigid ring. Here it is the C=N double bond that provides the constraint. If one of the alkyl chains is branched, more of the oxime with the OH group \textit{anti} to that chain will be formed and correspondingly more of the branched group will migrate.

Conditions that allow those double bond isomers to interconvert can allow either group to migrate— which one does so will then be decided, as in the Baeyer–Villiger reaction, by electronic factors. Most protic acids allow the oxime isomers to equilibrate, so, for example, this tosylated oxime rearranges with full stereospecificity in Al\(_2\)O\(_3\) (the \textit{anti} methyl group migrates), but with TsOH, equilibration of the oxime geometrical isomers means that either group could migrate—in the event, the propyl group (which is more able to support a positive charge) migrates faster.

Notice that the effect of the Beckmann rearrangement is to insert a nitrogen atom next to the carbonyl group. It forms a useful trio with the Baeyer–Villiger oxygen insertion and the diazoalkane carbon insertion.

**The Beckmann fragmentation**

To introduce the theme of the last section of this chapter, a Beckmann rearrangement that is not all that it seems. \( t \)-Butyl groups migrate well in the Baeyer–Villiger reaction and, indeed, Beckmann rearrangement of the compound in the margin appears to be quite normal too. But, when this compound and another compound with a tertiary centre next to the oxime are mixed together and treated with acid, it becomes apparent that what is happening is not an intramolecular reaction.
Each migrating tertiary group must have lost contact with the amide fragment it started out with. The molecule must fall apart to give a $t$-alkyl cation and a nitrile: the Beckmann rearrangement now goes via a fragmentation mechanism.

Migrating groups have to provide some degree of cation stabilization. But if they stabilize a cation too well there is a good chance that fragmentation will occur and the ‘migrating group’ will be lost as a carbocation.

Here is a more convincing example of the same fragmentation reaction: the conditions, but not the results, are those of a Beckmann rearrangement. In this reaction, the ring structure means the cation cannot be trapped by the nitrile, and a fragmentation product is isolated.

The mechanism is straightforward once you know what happens to Beckmann rearrangements when the migrating group is tertiary—but hard to follow unless you number the atoms!

Polarization of C–C bonds helps fragmentation

Up to now, you have met few fragmentation reactions—reactions in which C–C bonds are broken—largely because the C–C bond is so strong. Why then does the Beckmann...
For both carbon and hydrogen, a bond to oxygen is stronger than a bond to carbon. Yet we have no hesitation in breaking O–H bonds (of, say, carboxylic acids) with even the weakest of bases and we have spent much of this chapter showing C–O bonds of protonated alcohols rupturing spontaneously! What is going on?

The answer is polarization. Oxygen's electronegativity means that C–O and O–H bonds are polarized and are easy to break with hard nucleophiles and bases; C–C and C–H bonds are (usually) not polarized and, although weaker, are harder to break. It follows that to break a C–C bond it helps a lot if it is polarized—there needs to be a source of electrons at one end and an electron 'sink' (into which they can flow) at the other.

### Fragmentations require electron push and electron pull

Fragmentations are reactions in which the molecule breaks open by the cleavage of a C–C single bond, and we start this section with some examples. Both diastereoisomers of this cyclic diol fragment in acid to give an aldehyde.

Numbering the atoms shows which bond fragments—now we need to provide a source and a sink for the electrons to polarize the bond. Protonation of a hydroxyl group provides the sink—it can now leave as water. And the lone pair of the other oxygen provides the source. You can think of the electrons in the C–C bond being 'pushed' by the oxygen's lone pair and 'pulled' by the departing water—until the bond breaks. A bit of extra impetus comes from release of ring strain: C–C bonds in three- and four-membered rings are weaker than usual (by about 120 kJ mol$^{-1}$).

We talked about ‘pushing’ and ‘pulling’ electrons when we introduced the pinacol rearrangement, and a very similar thing is happening here but the electron source and sink are separated by one atom instead of being adjacent.

Protonated carbonyl compounds can be electron sinks too (remember the dienone-phenol rearrangement?) and this bicyclic methoxy ketone fragments to a seven-membered ring in acid. Note the same 1, 2, 3, 4 arrangement, with the bond between carbon atoms 2 and 3 fragmenting.
A leaving group such as mesylate can exercise the ‘pull’ and in the next example a carbonyl group provides the ‘push’ after it has been attacked by a nucleophile. This five-membered cyclic ketone fragments on treatment with base—can you detect hints of the benzylic acid rearrangement?

Analysing the Beckmann fragmentation on p. 960 in the same way, we can identify the electron sink (the departing acetate group), although the source in this case is a little more obscure. Saying that the tertiary cation is stable is really saying that the neighbouring C–C and C–H bonds provide electrons (through $\sigma$-conjugation, see p. 334) to stabilize it, so these are the electron sources (the ‘push’). A good alternative is to write loss of a proton concerted with fragmentation, which gives one particular C–H bond as the source of electrons.

The retro-aldol is a fragmentation reaction

We should perhaps remind you here of the reversibility of the aldol reaction (Chapter 26): a retro-aldol is a fragmentation reaction with a carbonyl group as electron sink and OH as electron source. The aldol reaction usually goes in the other direction of course, but where steric or ring-strain factors are involved, this may not be the case.

Fragmentations are controlled by stereochemistry

The control of rearrangements can be stereoelectronic in origin—if a molecule is to rearrange, orbitals have to be able to overlap. This means that, for a Beckmann rearrangement, the migrating group has to be trans to the leaving group. Not surprisingly, the same is true for Beckmann fragmentations like the one at the end of the last section, where the green fragmenting bond is trans to the leaving group. Before we extend these ideas any further, consider these two quite different reactions of quite similar compounds.
Just as with the rearrangements we looked at on p. 933, we need to draw these compounds in reasonable chair conformations in order to understand what is going on. In the cis isomer, both substituents can be equatorial; in the trans isomer one has to be axial, and this will be mainly the OTs group, since the two methyl groups of NMe₂ suffer greater 1,3-diaxial interactions.

Now, the cis isomer has clearly undergone a fragmentation reaction and, as usual, numbering the atoms can help to identify the bond that breaks. The nitrogen lone pair pushes, the departing tosylate pulls, and the resulting iminium ion hydrolyses to the product aldehyde.

Yet the trans isomer does this only in very low yield. Mostly it eliminates TsOH to give a mixture of alkenes. Why? Well, notice that, in the cis isomer, the fragmenting bond is trans to the leaving group—indeed, it is both parallel and trans (in other words anti-periplanar) to the leaving group. Electrons can flow smoothly from the breaking σ bond into the σ* of the C–OTs bond, forming as they do so a new π bond.

For the trans isomer, fragmentation of the most populated conformation is impossible because the leaving group is not anti-periplanar to any C–C bond. The only bonds anti-periplanar to OTs are C–H bonds, making this compound ideally set up for another reaction whose requirement for anti-periplanarity you have already met—E2 elimination.

The other conformation can fragment because now the OTs is anti-periplanar to the right C–C bond, and this is probably where the 11% fragmentation product comes from.

**Ring expansion by fragmentation**

Ring sizes greater than eight are hard to make. Yet five- and six-membered rings are easy to make. Once you realize that a fused pair of six-membered rings is really a ten-membered ring with a bond across the middle, the potential for making medium rings by fragmentation becomes apparent.

Interactive explanation of the stereochemistry of fragmentations
All you need to do is to make the bond to be broken the 2–3 bond in a 1, 2, 3, 4 electron source-sink arrangement and the ten-membered ring should appear out of the wreckage of the fragmentation. Here is an example:

This is the simple overall result, but there is more to explore. The starting hydroxytosylate can exist as four diastereoisomers: two trans-decalins and two cis-decalins. What is more, the product has a double bond in a ten-membered ring: will it be cis or trans? (Both are possible in a ring with more than eight members: see Chapter 29.) One of the four diastereoisomers of the starting material cannot place the tosylate anti-periplanar to the ring-fusion bond, so it can’t fragment. The other three diastereoisomers all can, but two of them give a trans double bond while the third gives cis.

Looking at the alignment of the bonds that end up flanking the double bond in the product shows you where the geometrical isomers come from: these are the black bonds in the starting material, and are trans across the forming $\pi$ system in the first two isomers and cis in the third. Fragmentations are stereospecific with regard to double-bond geometry, much as E2 elimination reactions are.

Caryophyllene by fragmentation
Corey applied this stereospecificity in conjunction with a ring expansion reaction to make the natural product caryophyllene. Caryophyllene is a bicyclic molecule with a nine-membered ring containing an $E$ trisubstituted double bond. The right relative stereochemistry in the starting material leads both to fragmentation of the right bond and to formation of the alkene with the right stereochemistry.

Muscone and exaltone are important perfumery compounds with even-harder-to-make 15-membered ring structures. Cyclododecanone is commercially available: addition of a fused five-membered ring and fragmentation of the 12,5-ring system is a useful route to these 15-membered ring compounds.
The Eschenmoser fragmentation

In the late 1960s, the Swiss chemist Albert Eschenmoser discovered an important reaction that can be used to achieve similar ring expansions and that now bears his name, the Eschenmoser fragmentation. The starting material for an Eschenmoser fragmentation is the epoxide of an \( \alpha,\beta \)-unsaturated ketone. The fragmentation happens when this epoxyketone is treated with tosylhydrazine, and one of the remarkable things about the product is that it is an alkyne. The fragmentation happens across the epoxide (shown in black), and the product contains both a ketone (in a different place from the ketone in the starting material) and an alkyne. You can see how in this case hydrogenation of the triple bond can give muscone (\( R = \text{Me} \)) or exaltone (\( R = \text{H} \)).

The Eschenmoser fragmentation does not have to be a ring expansion, and it is a useful synthetic method for making keto-alkynes. The following reaction, which we will use to discuss the fragmentation’s mechanism, was used to make an intermediate in the synthesis of an insect pheromone, \textit{exo}-brevicomin.

The reaction starts with formation of the tosylhydrazone from the epoxyketone. The tosylhydrazone is unstable with respect to opening of the epoxide in an elimination reaction, and it is this elimination that sets up the familiar 1, 2, 3, 4 system ready for fragmentation. The ‘push’ comes from the newly created hydroxyl group, and the ‘pull’ from the irresistible concerted loss of a good leaving group (Ts\(^-\)) and an even better one (N\(_2\)). Notice how all the (green) bonds that break are parallel to one another, held anti-periplanar by two double bonds. Perfect!

Controlling double bonds using fragmentation

Juvenile hormone (a compound you met in Chapter 27, p. 677) is a compound whose synthesis presents a major challenge: it requires the control of three trisubstituted double bonds (one of which ends up as an epoxide). The key intermediate shown contains two of them.
The chemists who succeeded in making this compound reasoned that, if this intermediate could be made stereospecifically by fragmenting a cyclic starting material, the (hard-to-control) double-bond stereochemistry would derive directly from the (easier-to-control) relative stereochemistry of the cyclic compound. The starting material they chose was a 5,6-fused system, which fragments to give one of the double bonds.

The product of this reaction is prepared for another fragmentation by addition of methyl-lithium (you might like to consider why you get this diastereoisomer) and tosylation of the less hindered secondary alcohol. Base promotes the second fragmentation and gives the ketone with the two double bonds in place.

In the next chapter you will meet, among many other reactions, more fragmentations, but they will be radical fragmentations rather than ionic fragmentations, and involve homolytic cleavage of C–C bonds.

**The synthesis of nootkatone: fragmentation showcase**

To finish this chapter, we will present three different synthetic routes to the same compound, all of which illustrate the power of fragmentation in the synthesis of cyclic compounds. The story starts with grapefruit, which contains a simple bicyclic enone called nootkatone. It was assumed, wrongly as it happens, that the scent of grapefruit came from this compound, and in the 1970s there was quite a rush to synthesize this compound in various laboratories. A remarkable feature of many successful syntheses was the use of fragmentation reactions. We shall describe parts of three syntheses involving the fragmentation of a six-, a four-, and a three-membered ring.

Most syntheses make the side-chain alkene by an elimination reaction so the first ‘disconnection’ is an FGI adding HX back into the alkene. The last C–C bond-forming operation in most syntheses is an intramolecular aldol reaction to make the enone so that can be disconnected next. It is the starting material for the aldol, a simple monocyclic diketone, which is usually made by a fragmentation reaction because this is a good way to set up the stereochemistry.
Fragmentation of a three-membered ring

This synthesis does not look as though it will lead to nootkatone because the fragmentation product still requires a great deal of modification. It has the advantage that the stereochemistry is correct at one centre at least. The sequence starts from natural (–)-carone: conjugate addition of the enolate to butenone without control leads to a bicyclic diketone with one extra stereogenic centre. The enone adds to the bottom face of the enolate opposite the dimethylcyclopropane ring so the methyl group is forced upwards.

Now the diketone is cyclized by a Robinson-style aldol condensation in HCl to give a bicyclic enone. But during the reaction, a new six-membered ring has been formed while the old three-membered ring has disappeared, evidently by fragmentation.

The fragmentation is pulled by the enone (with some help from the acid) and pushed by the stability of a tertiary carbocation as well as the release of strain as the single bond that is fragmented is in a three-membered ring.

Addition of a proton to the end of the enol and a chloride ion to the cation gives the product. The further development of this compound into nootkatone is beyond the scope of this book.

Fragmentation of a four-membered ring

This approach leads directly to the enone needed for nootkatone. A diketone prepared from a natural terpene is also treated with HCl and much the same reactions ensue except that the fragmentation now breaks open a four-membered ring. First, the intramolecular aldol reaction to make the second six-membered ring.

Now the fragmentation, which follows much the same course as the last one: the enone again provides the electron pull while the cleavage of a strained C–C single bond in a four-membered ring to give a tertiary carbocation provides the electron push. A simple elimination is all that is needed to make nootkatone from this bicyclic chloroenone.
Fragmentation of a six-membered ring

This chemistry is quite different from the examples we have just seen. The starting material has a bridged bicyclic structure and was made by a Diels–Alder reaction. Fragmentation is initiated by formic acid (HCO₂H), which protonates the tertiary alcohol and creates a tertiary carbocation. The ether provides the push. More serious electronic interactions are needed in this fragmentation as the C–C bond being broken is not in a strained ring.

The yield of 50% may not seem wonderful, but there is obviously a lot of chemistry going on here so it is perfectly acceptable when so much is being achieved. The first stage is the fragmentation itself. Drawing the product first of all in the same shape as the starting material and then redrawing, to ensure that we don’t make a mistake, we discover that we are well on the way to nootkatone. Note that the stereochemistry of the two methyl groups comes directly from the stereochemistry of the starting materials and no new stereogenic centres are created in the fragmentation. Although one six-membered ring is fragmented, another remains.

The first-formed product now cyclizes to form the second six-membered ring. This recreates a carbocation at the tertiary centre like the one that set off the fragmentation as the more nucleophilic end of the isolated alkene attacks the end of the conjugate electrophile. This is a thermodynamically controlled reaction with the new stereogenic centre choosing to have an equatorial substituent.

The cation picks up the only nucleophile available—formic acid. This gives the product of the fragmentation, which contains two unstable functional groups—a tertiary formate ester and an enol ether—and this product is not isolated from the reaction mixture. In water it hydrolyses to the enone, which undergoes elimination of formate to give nootkatone on heating.
Yet after all this effort, none of the synthetic samples of nootkatone delivered that intense grapefruit smell—for the simple reason that nootkatone is not the flavour principle of grapefruit! The samples of nootkatone that had been isolated from grapefruit contained minute traces of the true flavour principle—a simple thiol. Humans can detect $2 \times 10^{-5}$ ppb (parts per billion) of this compound, so even the tiniest trace is very powerful. Nonetheless, the syntheses allowed chemists to correct a misconception.

**Looking forward**

Fragmentation reactions cleave C–C single bonds by a combination of electron push and electron pull so that both electrons in the bond move in the same direction as the bond breaks. In the next chapter we shall see reactions that break C–C bonds in a quite different way. No electron push or pull is required because one electron goes one way and one the other. These are radical reactions.

**Further reading**

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Radical reactions

You may remember that at the beginning of Chapter 8 we said that the cleavage of H–Cl into H⁺ and Cl⁻ is possible in solution only because the ions that are formed are solvated: in the gas phase, the reaction is endothermic with \( \Delta G = +1347 \text{ kJ mol}^{-1} \), a value so vast that even if the whole universe were made of gaseous HCl at 273 K, not a single molecule would be dissociated into H⁺ and Cl⁻ ions. At temperatures above about 200 °C, however, HCl does begin to dissociate, but not into ions. Instead of the chlorine atom taking both bonding electrons with it, leaving a naked proton, the electron pair forming the H–Cl bond is shared out between the two atoms. \( \Delta G \) for this reaction is a much more reasonable +431 kJ mol⁻¹ and, at high temperatures (above about 200 °C, that is), HCl gas can be dissociated into H and Cl atoms.

\[
\begin{align*}
\text{HCl} & \rightarrow \text{gas phase} \rightarrow \text{H}^+ + \text{Cl}^- \\
\text{HCl} & >200 \degree C \rightarrow \text{H}^+ + \text{Cl}^- \\
\text{H}^+ & \quad 1 \text{ electron} \\
\text{Cl}^- & \quad 8 \text{ electrons in outer shell} \\
\text{HCl} & \quad 7 \text{ electrons in outer shell}
\end{align*}
\]

**Heterolysis and homolysis**

- When bonds break and one atom gets both bonding electrons, the process is called **heterolysis**. The products of heterolysis are, of course, ions.
- When bonds break and the atoms get one bonding electron each, the process is called **homolysis**. The products of homolysis are radicals, which may be atoms or molecules, but must contain an unpaired electron.
In Chapter 24 we introduced the fact that bromine radicals react regioselectively with alkenes. Let us remind you of one reaction you met then: radical addition to an alkene. The product is an alkyl bromide, and is a different alkyl bromide from the one formed when HBr adds to an alkene in an ionic manner.

What does the peroxide do to change the mechanism of the reaction? Peroxides undergo homolysis of the weak O–O bond extremely easily to form two radicals. We said that HCl in the gas phase undergoes homolysis in preference to heterolysis: other types of bond are even more susceptible to homolysis. You can see this for yourself by looking at this table of bond dissociation energies ($\Delta G$ for $X–Y \rightarrow X^* + Y^*$).

Dialkyl peroxides (dimethyl peroxide is shown in the table) contain the very weak O–O bond. The radicals formed by homolytic cleavage of these bonds, stimulated by a little heat or light, initiate what we call a radical chain reaction, which results in the formation of the Br• radicals, which add to the alkene’s C=C double bond (see Chapter 24).

**Radicals form by homolysis of weak bonds**

This is the most important way of making radicals: unpairing a pair of electrons by homolysis, making two new radicals. Temperatures of over 200 °C will homolyse most bonds; on the other hand, some weak bonds will undergo homolysis at temperatures little above room temperature. Light is a possible energy source for the homolysis of bonds too. Red light has associated with it 167 kJ mol$^{-1}$; blue light has about 293 kJ mol$^{-1}$. Ultraviolet (200 nm), with an associated energy of 586 kJ mol$^{-1}$, will decompose many organic compounds (including the DNA in skin cells: sunbathers beware!).

There are a number of compounds whose homolysis is particularly important to chemists, and the most important ones are discussed in turn below. They all have weak σ bonds, and generate radicals that can be put to some chemical use. The halogens are quite readily homolyzed by light, as you can see from the bond strengths in the table above, a fact that drives the radical halogenation reactions that we shall discuss later.

As you saw in Chapter 24, dibenzoyl peroxide is an important compound because it can act as another initiator of radical reactions. It undergoes homolysis simply on heating.
Another compound that is often used in synthetic reactions for the same reason (although it reacts with a different set of compounds) is AIBN (azobisisobutyronitrile).

\[ \Delta G^\ddagger = 131 \text{ kJ mol}^{-1} \]

This decomposition mechanism accounts for the separate movements of all the electrons, but we can also draw the mechanism in a slightly different way: we show two radical (‘fish hook’) arrows forming the molecule of nitrogen but only one arrow to break each of the C–N bonds. It can be assumed that the electrons ‘left behind’ form radicals as well.

Another way of cutting back on the number of arrows without losing precision in the mechanism is to draw one arrow for each step all in the same (which can be either) direction. The first mechanism has the advantage of complete clarity; the other two make for neater diagrams. Choose which suits you best.

The important thing is to use the right type of arrow and to make it clear whether you are moving one, and not two, electrons. A simpler example is the abstraction of a hydrogen atom by an oxygen-centred radical: any of the mechanisms below is fine.

**Radicals form by abstraction**

Notice that we didn’t put HBr on the list of molecules that form radicals by homolysis: relative to the weak bonds we have been talking about, the H–Br bond is quite strong (just about as strong as a C–C bond). We described in Chapter 24 how oxygen radicals abstract hydrogen atoms from HBr. You might now like to compare this mechanism with similar ionic reactions.

Hydrogen abstraction is the removal of a hydrogen atom with its one electron. It is not the removal of a proton: that would be the removal of a hydrogen atom with no electrons, which happens in ionic reactions.

The ability of radicals to propagate by abstraction is a key feature of radical chain reactions, which we shall come to later. There is an important difference between homolysis and abstraction as a way of making radicals: homolysis is a reaction of a spin-paired molecule that produces two radicals; abstraction is a reaction of a radical with a spin-paired molecule that produces one new radical and a new spin-paired molecule.
As the comparison above shows, radical abstractions are in fact substitution reactions (at \( \text{H} \) in this case). However, radical substitutions differ considerably from \( S_N^1 \) or \( S_N^2 \) reactions: importantly, radical substitutions almost never occur at carbon atoms. We shall come back to radical substitutions, or abstractions (depending on whether you take the point of view of the \( \text{H} \) atom or the \( \text{Br} \) atom), and explain why this should be, later in the chapter.

First radical detected

The very first radical to be detected, the triphenylmethyl radical, was made in 1900 by abstraction of \( \text{Cl}^* \) from \( \text{Ph}_3\text{CCl} \) by \( \text{Ag} \) metal. Many metal atoms such as \( \text{Ag}^* \) and \( \text{Li}^* \) have single unpaired electrons. This radical is relatively stable (we shall see why shortly), but reacts with itself reversibly in solution. The product of the dimerization of triphenylmethyl was for 70 years believed to be hexaphenyl ethane but, in 1970, NMR showed that it was, in fact, an unsymmetrical dimer.

Radicals form by addition

The key step in the radical addition of \( \text{HBr} \) to an alkyne in Chapter 24 was the formation of a radical by radical addition. The \( \text{Br}^* \) radical (which, you will remember, was formed by abstraction of \( \text{H}^* \) from \( \text{HBr} \) by \( \text{RO}^* \)) adds to the alkene to give a new, carbon-centred radical. This is the radical addition mechanism:

\[
\text{radical addition} \quad \text{Br}^* + \text{alkene} \rightarrow \text{carbon-centred radical}
\]

Just as charge must be conserved through a chemical reaction, so must the spin of the electrons involved. If a reactant carries an unpaired electron, then so must a product. Addition of a radical to a spin-paired molecule always generates a new radical. Radical addition is therefore a second type of radical-forming reaction.

The simplest radical addition reactions occur when a single electron is added to a spin-paired molecule. This process is a reduction. You have already met some examples of single-electron reductions: Birch reductions (Chapter 23) use the single electron formed when a Group I metal (sodium, usually) is dissolved in liquid ammonia to reduce organic compounds. Group I metals are common sources of single electrons: by giving up their odd s electron they form a stable \( \text{M}^+ \) ion. They will donate this electron to several classes of molecules, for example ketones can react with sodium to form ketyl radicals.

\[
\text{Na} + \text{alkene} \rightarrow \text{carbon-centred radical} + \text{M}^+
\]

We shall discuss ketyl radicals and their reactions on p. 980.
Radicals form by elimination

A fourth class of radical-forming reaction is elimination. For an example, we can go back to dibenzoyl peroxide, the unstable compound we considered earlier in the chapter. The radicals formed from dibenzoyl peroxide by homolysis are themselves unstable and each can break down by cleavage of a C–C bond, generating CO₂ and a phenyl radical. This is a radical elimination reaction, and is the reverse of a radical addition reaction.

\[
\begin{align*}
\text{dibenzoyl peroxide} & \xrightarrow{\text{homolysis}} \text{radical} \\
& \xrightarrow{\text{radical elimination}} \text{phenyl radical} + \text{CO}_2
\end{align*}
\]

To summarize methods of radical formation

Radicals form from spin-paired molecules by:

- homolysis of weak σ bonds, e.g.

\[
\text{RO} - \text{OR} \longrightarrow \text{RO}^+ \quad (\times 2)
\]

- electron transfer, that is, reduction (addition of an electron), e.g.

\[
\text{O} \quad \xrightarrow{\text{e}^-} \text{O}^-
\]

Radicals form from other radicals by:

- substitution (abstraction)

\[
\text{X}^+ \quad \text{Y} \quad \text{Z} \quad \longrightarrow \quad \text{X}^- \quad \text{Y}^- \quad \text{Z}^+
\]

- addition

\[
\text{X}^+ \quad \text{Y} \quad \text{Z} \quad \longrightarrow \quad \text{X} \quad \text{Y}^- \quad \text{Z}^+
\]

- elimination (homolysis)

\[
\text{X}^+ \quad \text{Y} \quad \text{Z} \quad \longrightarrow \quad \text{X} = \text{Y} \quad + \quad \text{Z}^+
\]

Most radicals are extremely reactive...

Unpaired electrons are desperate to be paired up again. This means that radicals usually have a very short lifetime; they don't survive long before undergoing a chemical reaction. Chemists are more interested in radicals that are reactive because they can be persuaded to do interesting and useful things. However, before we look at their reactions, we shall consider some radicals that are unreactive so that we can analyse the factors that contribute to radical reactivity.

...but a few radicals are very unreactive

Whilst simple alkyl radicals are extremely short-lived, some other radicals survive almost indefinitely. Such radicals are known as persistent radicals. We mentioned the triphenylmethyl...
radical on p. 973: this yellow substance exists in solution in equilibrium with its dimer, but it is persistent enough to account for 2–10% of the equilibrium mixture.

Persistent radicals with the single electron carried by an oxygen or a nitrogen atom are also known: these four radicals can all be handled as stable compounds. The first, known as TEMPO, is a commercial product and can even be sublimed.

Vitamin E tames radicals

Many of the molecules that make up the structure of human tissue are susceptible to homolysis in intense light, and the body makes use of sophisticated chemistry to protect itself from the action of the reactive radical products. Vitamin E plays an important role in the ‘taming’ of these radicals: abstraction of H from the phenolic hydroxyl group produces a relatively stable radical that does no further damage.

There are two reasons why some radicals are more persistent than others: (1) steric hindrance and (2) electronic stabilization. In the four extreme cases above, their exceptional stability is conferred by a mixture of these two effects. Before we can analyse the stability of other radicals, however, we need to look at what is known about the shape and electronic structure of radicals.

How to analyse the structure of radicals: electron spin resonance

For the last few pages we have been discussing the species we call radicals without offering any evidence that they actually exist. Well, there is evidence, and it comes from a spectroscopic technique known as electron spin resonance, or ESR (also known as EPR, electron paramagnetic resonance). ESR not only confirms that radicals do exist, but it can also tell us quite a lot about their structure.

Unpaired electrons, like the nuclei of certain atoms, have a magnetic moment associated with them. Proton NMR probes the environment of hydrogen atoms by examining the energy difference between the two possible orientations of their magnetic moments in a magnetic field; ESR works in a similar way for unpaired electrons. The magnetic moment of an electron is much bigger than that of a proton, so the difference in energy between the possible quantum
states in an electron field is also much bigger. This means that the magnets used in ESR spectrometers can be weaker than those in NMR spectrometers, usually about 0.3 tesla; even at this low field strength, the resonant frequency of an electron is about 9000 MHz (for comparison, the resonant frequency of a proton at 9.5 tesla is 400 MHz; in other words, a 400 MHz NMR machine has a magnetic field strength of 9.5 tesla).

But there are strong similarities between the techniques. ESR shows us, for example, that unpaired electrons couple with protons in the radical. The spectrum below is that of the methyl radical, \( \text{CH}_3 \). The 1:3:3:1 quartet pattern is just what you would expect for coupling to three equivalent protons; coupling in ESR is measured in millitesla (or gauss; 1 gauss = 0.1 mT), and for the methyl radical the coupling constant (called \( a_H \)) is 2.3 mT.

ESR hyperfine splittings (as the coupling patterns are known) can give quite a lot of information about a radical. For example, here is the hyperfine splitting pattern of the cycloheptatrienyl radical. The electron evidently sees all seven protons around the ring as equivalent, and must therefore be fully delocalized. A localized radical would see several different types of proton, resulting in a much more complex splitting pattern.

Even the relatively simple spectrum of the methyl radical tells us quite a lot about its structure. For example, the size of the coupling constant \( a_H \) indicates that the methyl radical is planar; the trifluoromethyl radical is, on the other hand, pyramidal. The oxygenated radicals \( \text{CH}_2\text{OH} \) and \( \text{CMe}_2\text{OH} \) lie somewhere in between. The calculations that show this lie outside the scope of this book.

**Radicals have singly occupied molecular orbitals**

ESR tells us that the methyl radical is planar: the carbon atom must therefore be \( sp^2 \) hybridized, with the unpaired electron in a \( p \) orbital. We can represent this in an energy level diagram.
In Chapter 4 we talked about the HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital) of organic molecules. CH₃ (like all radicals) has an orbital containing one electron, which we call a singly occupied molecular orbital (SOMO).

As with all molecules, it is the energy of the electrons in the molecular orbitals of the radical that dictate its stability. Any interaction that can decrease the energy levels of the filled molecular orbitals increases the stability of the radical (in other words, decreases its reactivity). Before we use this energy level diagram of the methyl radical to explain the stability of radicals, we need to look at some experimental data that allow us to judge just how stable different radicals are.

**Radical stability**

On p. 971 we used bond strength as a guide to the likelihood that bonds will be homolysed by heat or light. Since bond energies give us an idea of the ease with which radicals can form, they can also give us an idea of the stability of those radicals once they have formed.

\[ \Delta G = \text{energy required to homolyse bond} \]

\[ \Delta G = \text{energy released in combining radicals} \]

This is particularly true if we compare the strengths of bonds between the same atoms, for example carbon and hydrogen, in different molecules; this table does this.

A few simple trends are apparent. For example, C–H bonds decrease in strength in R–H when R goes from primary to secondary to tertiary. Tertiary alkyl radicals are therefore the most stable; methyl radicals the least stable.

C–H bonds next to conjugating groups such as allyl or benzyl are particularly weak, so allyl and benzy radical s are more stable. But C–H bonds to alkynyl, alkenyl, or aryl groups are strong. We saw the effects of this in Chapter 24.
Adjacent functional groups appear to weaken C–H bonds: radicals next to carbonyl, nitrile, or ether functional groups, or centred on a carbonyl carbon atom, are more stable than even tertiary alkyl radicals.

Whether the functional group is electron withdrawing or electron donating is clearly irrelevant here: both types seem to stabilize radicals. We can explain all of this if we look at how the different groups next to the radical centre interact electronically with the radical.

**Radicals are stabilized by conjugating, electron-withdrawing, and electron-donating groups**

Let’s consider first what happens when a radical centre finds itself next to an electron-withdrawing group. Groups like C=O and C≡N are electron withdrawing because they have a low-lying empty π* orbital. By overlapping with the (usually p) orbital containing the radical (the SOMO), two new molecular orbitals are generated. One electron (the one in the old SOMO) is available to fill the two new orbitals. It enters the new SOMO, which is of lower energy than the old one, and the radical experiences stabilization because this electron drops in energy.

We can analyse what happens with electron-rich groups, such as RO groups, in a similar way. Ether oxygen atoms have relatively high-energy filled n orbitals, their lone pairs. Interacting this with the SOMO again gives two new molecular orbitals. Three electrons are available to fill them. The SOMO is now higher in energy than it was to start with, but the lone pair is lower. Because two electrons have dropped in energy and only one has risen, there is an overall stabilization of the system, even though the new SOMO is of higher energy than the old one. We shall see later what effect the energy of the SOMO, rather than the overall energy of the radical, has on its reactivity.
In Chapter 15 you saw how the electrons in C–H σ bonds stabilize cations: they stabilize radicals in the same way, which is why tertiary radicals are more stable than primary ones. Conjugation, too, is effective at stabilizing radicals. We know from their ESR spectra (p. 976) that radicals next to double bonds are delocalized; that they are more stable is evident from the bond dissociation energies of allylic and benzylic C–H bonds.

---

**Anything that would stabilize an anion or a cation will stabilize a radical:**
- electron-withdrawing groups
- electron-donating groups (including alkyl groups with C–H σ bonds)
- conjugating groups.

---

**Steric hindrance makes radicals less reactive**

On p. 975 we showed you some radicals that are remarkably stable (persistent): some can even be isolated and purified. You should now be able to see at least part of the reason for their exceptional stability: two of them have adjacent powerful electron-donating groups, one has a powerful electron-withdrawing group as well, and three of the four are conjugated.

But electronic factors alone are not sufficient to explain the exceptional stability of all four radicals, since the two radicals on the right receive just about the same electronic stabilization as the first two above, but are much more reactive.

In fact, the stability of the triphenylmethyl radical we know to be due mainly to steric, rather than electronic, factors. X-ray crystallography shows that the three phenyl rings in this compound are not coplanar but are twisted out of a plane by about 30°, like a propeller. This means that the delocalization in this radical is less than ideal (we know that there is some delocalization from the ESR spectrum) and, in fact, it is little more delocalized than the diphenyldimethyl or even the benzyl radical, even though it is much more stable than either. This must be because the central carbon, which bears most of the radical character, is sterically shielded by the twisted phenyl groups, making it very hard for the molecule to react.
The rest of this chapter is devoted to the reactions of radicals, and you will see that the two effects we have talked about—electronic stabilization and steric hindrance—are key factors that control these reactions.

**How do radicals react?**

A reactive radical has a choice: it can either find another radical and combine to form a spin-paired molecule (or more than one spin-paired molecule), or it can react with a spin-paired molecule to form a new radical. Both are possible, and we shall see examples of each. A third alternative is for a radical to decompose in a unimolecular reaction, giving rise to a new radical and a spin-paired molecule.

- **Three possibilities:**
  - radical + radical $\rightarrow$ spin-paired molecule
    \[
    \begin{array}{c}
    \text{Br} \\
    \text{Br} \\
    \end{array}
    \xrightarrow{\text{Br} \quad \text{Br}} \quad \text{Br} - \text{Br}
    \]
  - radical + spin-paired molecule $\rightarrow$ new radical + new spin-paired molecule
    \[
    \begin{array}{c}
    \text{R}_1\text{O} \\
    \text{H} \\
    \text{R}_2 \\
    \end{array}
    \xrightarrow{\text{R}_1\text{O} \quad \text{H} \quad \text{R}_2} \quad \text{R}_1\text{OH} + \text{R}_2^*
    \]
  - radical $\rightarrow$ new radical + spin-paired molecule
    \[
    \begin{array}{c}
    \text{O} \\
    \text{C} \quad \text{O} \\
    \text{R} \\
    \end{array}
    \xrightarrow{\text{R} \quad \text{CO}_2} \quad \text{R}^* + \text{CO}_2
    \]

**Radical–radical reactions**

In view of the energy released when unpaired electrons pair up, you might expect this type of radical reaction to be more common than reaction with a spin-paired molecule, in which no net pairing of electrons takes place. Radical–radical reactions certainly do take place, but they are not the most important type of reaction involving radicals. We shall see why they are not as common as you might expect shortly, but first we can look at the few examples of radical–radical reactions which do work well.

**The pinacol reaction is a radical dimerization**

We outlined on p. 973 a way of making radicals by single electron transfer: effectively, the addition reaction of a single electron to a spin-paired molecule. The types of molecules that undergo this reaction are those with low-lying antibonding orbitals for the electron to go into, in particular aromatic systems and carbonyl compounds. The radical anion formed by addition of an electron to a ketone is known as a ketyl. The single electron is in the $\pi^*$ orbital, so we can represent a ketyl with the radical on oxygen or on carbon and the anion on the other atom.

Ketyl radicals behave in a manner that depends on the solvent that they are in. In protic solvents (ethanol, for example), the ketyl becomes protonated and then accepts a second electron from the metal (sodium is usually used in these cases). An alkoxide anion results, which, on addi-
tion of acid at the end of the reaction, gives an alcohol. Notice that this is a reaction using sodium metal in ethanol, and not sodium ethoxide, which is the basic product that forms once sodium has dissolved in ethanol. It is important that the sodium is dissolving as the reaction takes place, since only then are the free electrons available.

In aprotic solvents, such as benzene or ether, no protons are available so the concentration of ketyl radical builds up significantly and the ketyl radical anions start to dimerize. As well as being a radical–radical process, this dimerization process is an anion–anion reaction, so why doesn't electrostatic repulsion between the anions prevent them from approaching one another? The key to success is to use a metal such as magnesium or aluminium, which forms strong, covalent metal–oxygen bonds and can coordinate to more than one ketyl at once. Once two ketyls are coordinated to the same metal atom, they react rapidly.

The example shows the dimerization of acetone to give a diol (2,3-dimethylbutane-2,3-diol) whose trivial name, pinacol, is used as a name for this type of reaction using any ketone. Sometimes pinacol reactions create new chiral centres: in this example, the two diastereoismeric diols are formed in a 60:40 mixture. If you want to make a single diastereoisomer of a diol, a pinacol reaction is not a good choice!

**Benzophenone as an indicator in THF stills**

As you should have gathered by now, THF is an important organic solvent in which many low-temperature, inert atmosphere reactions are conducted. It has a drawback, however: it is quite hygroscopic, and often the reactions for which it is used as a solvent must be kept absolutely free of water. It is therefore always distilled immediately before use from sodium metal, which reacts with any traces of water in the THF. However, it is necessary to have an indicator to show that the THF is dry and that the sodium has done its job. The indicator used is a ketone, benzophenone.

When the THF is dry, the distilling liquid containing the benzophenone becomes bright purple. This colour is due to the ketyl of benzophenone, the formation of which under these conditions should not surprise you. It should also come as no surprise that this ketyl, being stabilized by conjugation and quite hindered, is persistent (long-lived)—it does not undergo pinacol dimerization (as we explained above, you would not normally choose sodium to promote pinacols anyway). However, if water is present, the ketyl is rapidly quenched in the manner of the reduction described above to give the (colourless) alkoxide anion: only when all the water is consumed does the colour return.
Pinacol reactions can be carried out intramolecularly, from compounds containing two carbonyl groups. In fact, the key step of one of the very first syntheses of the important anti-cancer compound Taxol was an intramolecular pinacol reaction using titanium as the source of electrons.

The titanium metal that is the source of electrons is produced during the reaction by reduction of TiCl₃ using a zinc–copper mixture. This reaction is, in fact, unusual because, as we shall see below, pinacol reactions using titanium do not normally stop at the diol, but give alkenes.

**Titanium promotes the pinacol coupling and then deoxygenates the products: the McMurry reaction**

Titanium can be used as the metal source of electrons in the pinacol reaction and, provided the reaction is kept cold and not left for too long, diols can be isolated from the reaction, as in the example above. However, unlike magnesium or aluminium, titanium reacts further with these diol products to give alkenes in a reaction known as the McMurry reaction, after its inventor.

Notice that the titanium(0), which is the source of electrons in the reaction, is produced during the reaction by reacting a Ti(III) salt, usually TiCl₃, with a reducing agent such as LiAlH₄ or Zn/Cu. The reaction does not work with, say, powdered titanium metal. The McMurry reaction is believed to be a two-stage process involving firstly a pinacol radical–radical coupling.

The Ti(0) then proceeds to deoxygenate the diol by a mechanism not fully understood, but thought to involve binding of the diol to the surface of the Ti(0) particles produced in the reduction of TiCl₃.
We expect you to be mildly horrified by the inadequacy of the mechanism above. But, unfortunately, we can’t do much better because no-one really knows quite what is happening. The McMurry reaction is very useful for making tetrasubstituted double bonds—there are few other really effective ways of doing this. However, the double bonds really need to be symmetrical (in other words, have the same substituents at each end) because McMurry reactions between two different ketones are rarely successful.

\[
\text{TiCl}_3, \text{Zn/Cu} \quad 96\% \text{ yield}
\]

McMurry reactions also work very well intramolecularly, and turn out to be quite a good way of making cyclic alkenes, especially when the ring involved is medium or large (over about eight members). For example, the natural product flexibilene, with a 15-membered ring, can be made by cyclizing a 15-keto-aldehyde.

\[
\text{O} \quad \text{H} \quad \text{O} \\
\begin{array}{c}
\text{O} \\
\text{Et} \\
\text{NaO} \\
\text{Et}_2\text{O}
\end{array} \\
\text{O} \quad \text{O} \quad \text{O} \\
\begin{array}{c}
\text{O} \\
\text{Et} \\
\text{NaO} \\
\text{Et}_2\text{O}
\end{array}
\]

**Esters undergo pinacol-type coupling: the acyloin reaction**

You’ve seen examples of pinacol and McMurry reactions of ketones and aldehydes. What about esters? You would expect the ketyl radical anion to form from an ester in the same way, and then to undergo radical dimerization, and this is indeed what happens.

\[
\text{NaO} \quad \text{Na} \\
\text{EtO} \quad \text{OEt} \\
\begin{array}{c}
\text{NaO} \\
\text{EtO} \\
\text{OEt}
\end{array}
\]

The product of the dimerization looks very much like a tetrahedral intermediate in a carbonyl addition–elimination reaction, and it collapses to give a 1,2-diketone.

\[
\text{EtO} \quad \text{OEt} \\
\begin{array}{c}
\text{EtO} \\
\text{OEt}
\end{array}
\]

The diketone is, however, still reducible—in fact, 1,2-diketones are more reactive towards electrophiles and reducing agents than ketones because their $\pi^*$ is lower in energy and straight away two electron transfers take place to form a molecule, which we could term an **enediolate**. On quenching the reaction with acid, this dianion is protonated twice to give the enol of an $\alpha$-hydroxy-ketone, and it is this $\alpha$-hydroxy-ketone that is the final product of the acyloin reaction. The yield in this example is a quite respectable 70%. However, in many other cases, this usefulness of the acyloin reaction is hampered by the formation of by-products that arise because of the reactivity of the enediolate dianion. It is, of course, quite nucleophilic, and is likely to be formed in the presence of the highly electrophilic diketone. It is also basic, and often catalyses a competing Claisen condensation of the esters being reduced.
The solution to these problems is to add trimethylsilyl chloride to the reaction mixture. The silyl chloride silylates the enediolate as it is formed, and the product of the acyloin reaction becomes a bis-silyl ether.

These silyl ethers are rarely wanted as final products, and they can easily be hydrolysed to $\alpha$-hydroxyketones with aqueous acid. This improved version makes four-membered rings efficiently.

It’s not by accident that these two examples of the acyloin reaction show the formation of cyclic compounds. It is a particularly powerful method of making carbocyclic rings from four-membered upwards: the energy to be gained by pairing up the two electrons in the radical–radical reaction step more than compensates for the strain that may be generated in forming the ring.

The pinacol, McMurry, and acyloin reactions are exceptional

We’ve already said that this type of reaction, in which two radicals dimerize, is relatively uncommon. Most radicals are simply too reactive to react with one another! This may sound nonsensical, but the reason is simply that highly reactive species are unselective about what they react with. Although it might be energetically favourable for them to find another radical and dimerize, they are much more likely to collide with a solvent molecule, or a molecule of some other compound present in the mixture, than another radical. Reactive radicals are only ever present in solution in very low concentrations, so the chances of a radical–radical collision are very low. Radical attack on spin-paired molecules is much more common and, because the product of such reaction is also a radical, they give rise to the possibility of radical chain reactions.

Radical chain reactions

In looking at how radicals form, you’ve already seen examples of how radicals react. In fact, we’ve already dealt (if only very briefly) with every step of the sequence of reactions that makes up the mechanism of the radical reaction you met at the beginning of the chapter, and shown below.
Let's now consider each step in turn and in more detail.

1. The dialkyl peroxide is homolysed (by heat or light) to give two alkoxy radicals.

2. RO\textsuperscript* abstracts H from HBr (radical substitution) to give Br\textsuperscript*.

3. Br\textsuperscript* adds to isobutene to give a carbon-centred radical.

4. The carbon-centred radical abstracts a hydrogen atom from H–Br to form the final addition product and regenerate Br\textsuperscript*, which can react with another molecule of alkene.

So the whole process is a cycle with the bromine radical regenerated in the last step, the one in which the product is formed.

In each step in the cycle a radical is consumed and a new radical is formed. This type of reaction is therefore known as a radical chain reaction, and the two steps that form the cyclic process that keeps the chain running are known as the chain propagation steps. Only one molecule of peroxide initiator is necessary for a large number of product molecules to be formed and, indeed, the peroxide needs to be added in only catalytic quantities (about 10 mol%) for this reaction to proceed in good yield.

Any less than 10 mol%, however, and the yield drops. The problem is that the chain reaction is not 100% efficient. Because the concentration of radicals in the reaction mixture is low, radical–radical reactions are rare, but nonetheless they happen often enough that more peroxide keeps being needed to start the chain off again.

Reactions like this are known as termination steps and are actually an important part of any chain reaction; without termination steps the reaction would be uncontrollable.
Selectivity in radical chain reactions

In the radical–radical reactions we looked at earlier, there was never any question of what would react with what: only one type of radical was formed and the radicals dimerized in identical pairs. Look at the chain reaction above though—there are three types of radical present, Br•, BrCH2Me2CH•, and RO•, and they all react specifically with a chosen spin-paired partner: Br• with the alkene, and BrCH2Me2CH• and RO• with HBr. We need to understand the factors that govern this chemoselectivity. In order to do so we shall look at another radical reaction with chemoselectivity and regioselectivity that is measurable.

Chlorination of alkanes

Alkanes will react with chlorine radicals to give alkyl chlorides. For example, cyclohexane plus chlorine gas, in the presence of light, gives cyclohexyl chloride and hydrogen chloride.

\[
\text{Cyclohexane} + \text{Cl}_2 \xrightarrow{hv} \text{Cyclohexyl chloride} + \text{HCl}
\]

The Toray process

A variant of this reaction, known as the Toray process, is used on an industrial scale to produce caprolactam, a precursor to nylon. Instead of chlorine, nitrosyl chloride is used to form a nitroso compound that rapidly tautomerizes to an oxime. As you saw in Chapter 36, this oxime undergoes a Beckmann rearrangement under acid conditions to form caprolactam.

Interactive mechanism for radical addition of Cl₂ to cyclohexane

Interactive mechanism for radical termination steps

We have already suggested two reasons why the Br• radical adds to the alkene with this characteristic regioselectivity, giving a primary alkyl bromide when the polar addition of HBr to an alkene would give a tertiary alkyl bromide: (1) attack at the unsubstituted end of the alkene is less sterically hindered and (2) the tertiary radical thus formed is more stable than a primary radical. In fact, of all the hydrogen halides, only HBr will add to alkenes in this fashion: HCl and HI will undergo only polar addition to give the tertiary alkyl halide. Why? We need to be able to answer this type of question too.
event (photolysis of chlorine). Be warned: reactions like this can be explosive in sunlight and are carried out in specialized facilities, not in the open laboratory.

When the chlorine radical abstracts a hydrogen atom from the cyclohexane, only one product can be formed because all 12 hydrogen atoms are equivalent. For other alkanes this may not be the case, and mixtures of alkyl chlorides can result. For example, propane is chlorinated to give a mixture of alkyl chlorides containing 45% 1-chloropropane and 55% 2-chloropropane, and isobutane is chlorinated to give 63% iso-butyl chloride and 37% tert-butyl chloride.

How can we explain the ratios of products that are formed? The key is to look at the relative stabilities of the radicals involved in the reaction and the strengths of the bonds that are formed and broken. First, the chlorination of propane. A chlorine radical, produced by photolysis, can abstract either a primary hydrogen atom, from the end of the molecule, or a secondary hydrogen atom, from the middle. For the two processes, we have these energy gains and losses:

<table>
<thead>
<tr>
<th>Abstraction</th>
<th>ΔH, kJ mol⁻¹</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary</td>
<td>-431</td>
</tr>
<tr>
<td>Secondary</td>
<td>+423</td>
</tr>
<tr>
<td>Total</td>
<td>-8</td>
</tr>
</tbody>
</table>

Abstraction of the secondary hydrogen atom is more exothermic than abstraction of the primary hydrogen atom for the related reasons that: (1) secondary C–H bonds are weaker than primary ones and (2) secondary radicals are more stable than primary ones. So, we get more 2-chloropropane than 1-chloropropane. But in this case, that isn’t the only factor involved: remember that there are six primary hydrogen atoms and only two secondary ones, so the relative reactivity of the primary and secondary positions is even more different than the simple ratio of products from the reaction suggests. This statistical factor is more evident in the second example we gave above, the chlorination of isobutane. Now the choice is between formation of a tertiary radical and formation of a primary one.

<table>
<thead>
<tr>
<th>Abstraction</th>
<th>ΔH, kJ mol⁻¹</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary</td>
<td>-431</td>
</tr>
<tr>
<td>Tertiary</td>
<td>+397</td>
</tr>
<tr>
<td>Total</td>
<td>-34</td>
</tr>
</tbody>
</table>

Tertiary radical formation is more exothermic, yet more primary alkyl chloride is formed than tertiary alkyl chloride. However, once the 9:1 ratio of primary to tertiary hydrogen atoms is taken into account, the relative reactivities, as determined experimentally, turn out to be as shown in the table below.
The rate of attack by Cl• on a tertiary C–H bond, then, is about five times the rate of attack by Cl• on a primary C–H bond. We said that this is because the formation of the tertiary radical is more exothermic than the formation of the primary radical. But the rate of a reaction depends not on Δ\( \text{H} \) for that reaction but on the activation energy of the reaction; in other words, the energy needed to reach the transition state for the reaction. But we can still use the stability of the product radicals as a guide to the stability of the transition state because the transition state must have significant radical character.

The energy diagram above illustrates this point. As the reactants (Cl• plus isobutane) move towards the products, they pass through a transition state (TS\(_3\) for formation of the primary radical, TS\(_3\) for formation of the tertiary) in which the radical character of the Cl• starting material is spread over both the Cl and the C centres. The greater stability of a tertiary radical compared with a primary one must be reflected to a lesser degree in these transition states: a radical shared between Cl and a tertiary centre will be more stable than a radical shared between Cl and a primary centre. The transition state TS\(_3\) for the reaction at the tertiary C–H bond is therefore of lower energy than the transition state TS\(_1\) for reaction at the primary C–H bond. In other words, the activation energy Δ\( G^\ddagger \) is smaller than Δ\( G^\ddagger \), so reaction at the tertiary C–H bond is faster.

**Bromination of alkanes is more selective**

Bromine will also halogenate alkanes, and it does so much more selectively than chlorine. For example, the following reaction yields tert-butyl bromide with less than 1% of the primary isomer.

\[
\text{Br}_2 \xrightarrow{h\nu} \text{Br}^+ + \text{Br}^- \]

\[
\rightarrow \text{Br}^- + \text{tert-Br} \text{Br}^- >99% <1%\]

In this case, the first step of the radical chain reaction, the abstraction of H by Br•, is endothermic for both the primary and tertiary hydrogen atoms, but more so for primary radical formation, so the tertiary radical is preferred.
Of course, in both brominations and chlorinations the overall reaction is favourable because the second step—the halogenation of the alkyl radical—is significantly exothermic, by about 106 kJ mol\(^{-1}\) for chlorination and about 83 kJ mol\(^{-1}\) for bromination. The same is true for fluorination, but with fluorine this step is so exothermic that fluorination becomes dangerously explosive. Conversely, radical iodination is impossible because the final step is insufficiently exothermic to make up for the endothermic formation of an alkyl radical.

Why is bromination so much more selective than the chlorination of alkanes? This is a good example of the Hammond postulate, applied to real chemistry. Because the products of the first step of the bromination (R\(^•\) plus HBr) are higher in energy than the starting materials, the transition state must be similar in structure and energy to the radical being formed; the difference in energies of the primary and tertiary product radicals should therefore be markedly reflected in the different energies of the transition states TS\(_1\) and TS\(_3\), and \(\Delta G_1^\ddagger\) will be significantly larger than \(\Delta G_3^\ddagger\). For the chlorination reaction, the products were just slightly lower in energy than the starting materials, so the transition states for the two possible reactions both resembled the starting materials rather more and the products rather less. These are the same for both tertiary and primary hydrogen abstractions, of course, so the difference in energy of the product radicals exerts a less pronounced effect on the difference in energy of the transition states.

**Allylic bromination**

Because radical brominations are so selective, they can be used successfully in the laboratory to make alkyl bromides. There are relatively few ways of functionalizing an unfunctionalized centre, and radical allylic bromination is one of the most effective. We introduced this reaction in Chapter 24, where we contrasted the radical reactivity of Br\(_2\) towards alkenes (leading to an allyl bromide by hydrogen abstraction) with its ionic reactivity (leading to addition of bromine across the alkene). We can now look in a little more detail at the selectivities involved.
Here is a typical allylic bromination. NBS (N-bromosuccinimide) is used to form a small amount of Br₂ and to keep the Br₂ concentration low.

\[
\begin{align*}
\text{NBS, CCl₄, } h\nu &\rightarrow \text{Br₂} & \text{85% yield} \\
\end{align*}
\]

Photolysis of Br₂ initiates the reaction, which then propagates as shown below. The mechanism also illustrates the first aspect of selectivity: only a (green) allylic H atom is abstracted because an allylic C–H bond is considerably weaker than a secondary C–H bond (364 vs. 410 kJ mol⁻¹ from the table on p. 977).

There is a problem with this reaction if bromine itself is used because an alternative radical addition reaction can compete with radical abstraction.

The first step of this competing addition reaction is reversible; the reaction is driven forward by the participation of a second molecule of bromine that traps the product alkyl radical. This side reaction can be prevented if the concentration of Br₂ in the reaction is kept very low, which is the role of NBS. The alternative competing polar addition of Br₂ to the alkene is likewise prevented with the low bromine concentration provided by NBS, although the non-polar solvent CCl₄ also disfavours the formation of the cationic bromonium ion intermediate.

While radical halogenation of alkanes is used only rarely in the laboratory, radical allylic bromination of alkenes is a versatile and commonly used way of making allylic bromides. Nucleophilic substitution reactions can then be used to convert the bromide to other functional groups. For example, some chemists in Manchester needed to make the two diastereoisomers of 5-tert-butyl-cyclohex-2-en-1-ol to study their reactions with osmium tetroxide. tert-Butyl cyclohexene is readily available, so they used a radical allylic bromination to introduce the functional group in the allylic position, which they converted to a hydroxyl group using aqueous base. Steric effects also play a role here in the regioselectivity of the reaction: only the less hindered allylic hydrogen atoms further from the tert-butyl group are removed.

\[
\begin{align*}
\text{NBS, CCl₄, H₂O, K₂CO₃} &\rightarrow \text{both formed as mixtures of diastereoisomers} \\
\end{align*}
\]

**Reversing the selectivity: radical substitution of Br by H**

Radical substitution reactions can also be used to *remove* functional groups from molecules. A useful reagent for this (and, as you will see, for other radical reactions too) is tributyltin.
hydride, Bu₃SnH. The Sn–H bond is weak and Bu₃SnH will react with alkyl halides to replace the halogen atom with H, producing Bu₃SnHal as a by-product.

Clearly, for this reaction to be energetically favourable, the new bonds formed (Sn–Br and C–H) must be stronger than the old bonds broken (Sn–H and C–halogen). Look at this table of average bond energies and you will see that this is indeed so. The use of a tin hydride is crucial to this reaction: Sn–H bonds are weaker than Sn–Br bonds, while, for carbon, C–H bonds are stronger. Bu₃SnH is therefore an effective source of Bu₃Sn• radicals, and the Bu₃Sn• radical will abstract halogens, particularly I or Br, but also Cl, from organic halides, breaking a weak C–halogen (C–Hal) bond and forming a strong Sn–Hal bond. The complete mechanism of the reaction reveals a chain reaction.

Homolysis of Bu₃SnH is promoted by the initiator AIBN

As you would imagine, the weakest C–Hal bonds are the easiest to cleave, so alkyl bromides are reduced more rapidly than alkyl chlorides, and alkyl fluorides are unreactive. With alkyl iodides and bromides, daylight can be sufficient to initiate the reaction, but with alkyl chlorides, and often with alkyl bromides as well, it is generally necessary to produce a higher concentration of Bu₃Sn• radicals by adding an initiator to the reaction. The best choice is usually AIBN, which you met earlier in the chapter (p. 972). This compound undergoes thermal homolysis above 60 °C to give nitrile-stabilized radicals that abstract the hydrogen atom from Bu₃SnH.

Why use AIBN as an initiator; why not a peroxide? Since we want to cleave only a weak Sn–H bond, we can get away with using a relatively unreactive nitrile-stabilized radical. Peroxides, on the other hand, generate RO• radicals. These are highly reactive and will abstract hydrogen from almost any organic molecule, not just the weakly bonded hydrogen atom of Bu₃SnH, and this would lead to side reactions and lack of selectivity. AIBN is needed only in sufficient quantities to be an initiator of the reaction; it is the Bu₃SnH that provides the hydrogen atoms that end up in the product, so usually you need only 0.02 to 0.05 equivalents of AIBN and a slight excess (1.2 equivalents) of Bu₃SnH.
Carbon–carbon bond formation with radicals

You have now met these examples of radical chain reactions:

1. radical addition of halogens to double bonds
2. radical substitution of hydrogen by halogens, or of halogens by hydrogen.

You have seen how the selectivity of these reactions depends upon the bond strengths of the bond being formed or broken. Until about 1975, these reactions, with a few exceptions, were all that were expected of radicals. Since that date, however, the use of radicals in synthetic chemistry has increased tremendously, to the point where complex ring structures such as those of the natural product hirsutene or the steroids can be made from simple acyclic precursors in one radical-promoted step.

What has made this all possible is that chemists have learned how to understand the selectivity of radical reactions to such a degree that they can design starting materials and reagents to define precisely the bonds that will break and form during the reactions. We shall now go on to look at the most important consequence of this ability to control radical reactions: they can be used to make carbon–carbon bonds.

The radical reaction in the margin forms a new carbon–carbon bond. The mechanism is quite similar to that of the very first radical reaction we showed you, right at the beginning of the chapter. Now, with your additional appreciation of the role of bond strength in the selectivity of radical reactions, you should be able to understand why each step proceeds in the way that it does.

First the weakest bond, C–Br, is broken by the light being shone on to the reaction. Two radicals form, CCl₃• and Br•, and it is the CCl₃• that adds to the (less hindered) unsubstituted end of the alkene to produce a (more stable) secondary benzylic radical.

This radical abstracts a Br atom from the BrCCl₃, breaking the (weakest) C–Br bond, forming the product, and regenerating •CCl₃, which adds to another molecule of alkene. Notice that the carbon-centred radical abstracts Br* and not •CCl₃ from BrCCl₃—to abstract •CCl₃ would require a radical substitution at carbon—remember, radicals want the easy pickings from the front of the display; they don’t go nosing round the back to see if there’s anything better to be had.

This reaction works quite well, giving 78% of the product, but it relies on the fact that the starting material, BrCCl₃, has an unusually weak C–Br bond (the •CCl₃ radical is highly stabilized by those three chlorine atoms). You can’t use most other alkyl bromides for a number of reasons, not least of them being that the product is also an alkyl bromide and, without the selectivity provided by the CCl₃ group, the result would be a mixture of polymers. The problem is that we want the product radical to abstract Br from the starting alkyl bromide to make...
a new alkyl bromide and a new starting radical, and there is no energetic driving force behind this transformation.

For a way of overcoming this problem, let’s go back to the reaction we looked at a few pages ago, the dehalogenation of alkyl halides by Bu₃SnH. The mechanism involves formation of an alkyl (carbon-centred) radical by abstraction of Br by Bu₃Sn•. This alkyl radical then just abstracted H• from Bu₃SnH.

Is it not possible to use this alkyl radical more constructively, and encourage it to react with another molecule (an alkene, say, as •CCl₃ did)? The answer is a qualified yes: look at this reaction:

We have added a carbon-centred radical to an alkene in a radical chain reaction! Here is the mechanism:

Something important has happened here: the product radical no longer has to abstract the halogen from the starting material, but instead has to abstract H from Bu₃SnH; it is the Bu₃Sn• thus formed that then regenerates the starting radical. The driving force is provided by formation of C–H at the expense of Sn–H and then Sn–Br at the expense of C–Br.

The use of tin hydrides increases the power of radical reactions in organic synthesis tremendously, and all of the steps in these radical chain processes have been studied in great detail because of the importance of the reactions. We won’t dwell excessively on these details, but we need to go back and re-examine some points about this reaction because there are some further subtleties that you need to understand. Bear in mind that we have four radicals all in the reaction mixture at the same time. Yet each reacts with its chosen partner, forsaking all others.

Let’s take each type of radical in turn, and look at its selectivity. Clearly bond strength has something to do with this, but how do you explain the opposing selectivities of R• and the nitrile-stabilized radicals? We shall see that the origins of the selectivities impose some restrictions on the type of starting material that can be used for these C–C bond-forming reactions.
For the tin radical, Bu₃Sn•, there is a choice of reaction partners: we need it to abstract the halide from the starting material, but it could alternatively add to the alkene. The Sn–C bond is relatively weak, so addition to the alkene becomes a significant reaction only if:

- there is a large excess of alkene present, and
- the starting alkyl halide is relatively unreactive. This means that only alkyl bromides and iodides can be used effectively to form carbon–carbon bonds; alkyl chlorides are just too unreactive.

The contrasting reactivity of the alkyl radical R• and the nitrile-containing radicals needs a little more analysis, and we will look at how both concentration and electronics affect their selectivities.

**Concentration effects**

You know that R• is perfectly capable of abstracting H from Bu₃SnH because that is what happened in the dehalogenation reaction on p. 991, but here a different reaction happens: addition to the alkene. In fact, the rate constant for reaction of R• with Bu₃SnH is about the same as that for reaction with acrylonitrile (CH₂=CHCN), so the only way in which good yields can be obtained is by ensuring that the concentration of acrylonitrile is always at least 10 times that of the tin hydride. The difference in rates will then be sufficient to give 10 times as much addition to the alkene as reduction by the tin hydride. Too much acrylonitrile in the reaction mixture causes problems with side reactions, so a good way of achieving this is to add the tin hydride very slowly during the reaction—often a device known as a syringe pump is used for this. Of course, for complete reaction, a whole equivalent of hydride is necessary, but this can be added over a period of hours.

An elegant alternative is to use a technique conceptually similar to the use of NBS to provide a low concentration of Br₂ for radical allylic substitution. Instead of adding one equivalent of Bu₃SnH, a catalytic amount (usually 0.1–0.2 equivalents) of Bu₃SnCl is added at the beginning of the reaction, with 1 equivalent of NaBH₄. NaBH₄ will reduce Bu₃SnHal to Bu₃SnH, so about 0.1 equivalent of Bu₃SnH is formed immediately. With each cycle of the chain reaction, a molecule of this Bu₃SnH is converted to Bu₃SnBr, which NaBH₄ can reduce back to Bu₃SnH. Only as much Bu₃SnH is produced as is needed because the rate of production is limited by the rate of reaction.

This method was used in the following example, in which an enantiomerically pure lactone, a useful synthetic building block, was made from naturally occurring glyceraldehyde.
Frontier orbital effects

The second key to success in making sure that the alkyl radical behaves well is to use a reactive radical trap. In fact, this is a major limitation of intermolecular radical carbon–carbon bond-forming reactions: for the trapping of alkyl radicals only electrophilic alkenes (attached to electron-withdrawing groups such as –CN, –CO₂Me, and –COMe) will do. This is a limitation, but nonetheless cyclohexyl iodide adds to all these alkenes with the yields shown and the rate of addition to most of these alkenes is 10¹ to 10⁴ times that of addition to 1-hexene.

To explain why, we have to go back to our analysis (on p. 978) of the electronic structure of radicals and the energy of SOMOs. We said there that, while both electron-withdrawing groups and electron-donating groups will stabilize radicals, electron-withdrawing groups tend to lower the energy of the SOMO, while electron-donating groups tend to raise the energy of the SOMO.

Electrophilic and nucleophilic radicals

- **Low-energy SOMOs** are more willing to accept an electron than to give one up; radicals adjacent to electron-withdrawing groups are therefore **electrophilic**.
- **High-energy SOMOs** are more willing to give up an electron than to accept an electron; radicals adjacent to electron-donating groups are therefore **nucleophilic**.

Hence the preferred reactivity of these alkyl radicals: they are relatively nucleophilic and therefore prefer to react with electrophilic alkenes. Reaction between a nucleophilic alkyl radical and an unfunctionalized (and therefore nucleophilic) alkene is much slower. Similarly, radicals adjacent to electron-withdrawing groups do not react well with electrophilic alkenes. We can represent all this on an energy level diagram.
We can now consider the third type of radical in the reaction mixture highlighted on p. 993—the nitrile-stabilized alkyl radicals. The diagram above explains the third aspect of radical chemoselectivity in the reaction: why both the product radical and the radicals produced by AIBN choose to react with Bu₃SnH and not with acrylonitrile. These radicals are electrophilic—they have an electron-withdrawing nitrile group attached to the radical centre, so reaction with an electron-poor alkene is slow.

### Summary of requirements for the successful use of the tin method

**Electrophilic radicals**

Having seen the energy diagram above, you will not be surprised to learn that the malonate radical adds readily to nucleophilic alkenes, but to nucleophilic alkenes, such as this vinyl ether, which carries an electron-donating oxygen substituent. The malonate radical is electron deficient; it has a low-energy SOMO which interacts best with the relatively high-energy HOMO of the electron-rich, nucleophilic alkene.
This difference in reactivity applies to non-carbon-centred radicals too. For example, the methyl radical ‘CH₃’ and the chlorine radical Cl· will both abstract a hydrogen atom from propionic acid. As you would expect, the methyl radical abstracts the hydrogen atom from next to the carbonyl group to form a carbonyl-stabilized radical. Perhaps surprisingly (in view of what we said earlier about the selectivity of radical chlorinations), the chlorine radical abstracts a hydrogen atom from the terminal methyl group of the acid, despite the fact that this C–H bond is stronger. The reason has to be to do with HOMO–LUMO interactions. The methyl radical is nucleophilic, with a high-energy SOMO. It therefore attacks the C–H bond with the lowest LUMO, in other words, α to the carbonyl group. The chlorine atom, on the other hand, is electrophilic: it has a low-energy SOMO (because it is an electronegative element) and attacks the C–H bonds of the terminal methyl group because they have the highest-energy HOMO. Chlorination of functionalized compounds is not as straightforward as that of simple alkanes!

**Copolymerization**

Radical chain reactions are particularly suited to the synthesis of polymers, and there is one example of a polymerization that is worth including here since it demonstrates very nicely the effect of electron-withdrawing or -donating substituents on radical reactivity. When a mixture of vinyl acetate and methyl acrylate is treated with a radical initiator, a rather remarkable polymerization takes place. The polymer produced contains *alternating* vinyl acetate and methyl acrylate monomers along the length of its chain.

The mechanism of the reaction shows you why. The nucleophilic radical from vinyl acetate (adjacent to filled n orbital of OAc; high-energy SOMO) prefers to add to the electrophilic alkene (the acrylate). The new radical (adjacent to the empty π* orbital of CO₂Me; low-energy SOMO) is electrophilic and prefers to add to nucleophilic alkene (the vinyl acetate). This produces a new nucleophilic radical, which again prefers to add to the electrophilic alkene, and the whole cycle occurs repeatedly.

The radical produced by addition to vinyl acetate is nucleophilic, so it adds to methyl acrylate; the radical produced by addition to methyl acrylate is electrophilic, so it adds to vinyl acetate. This reaction is a clear demonstration of the power of frontier orbital theory to explain the reactivity of organic molecules—it would be hard to come up with any other convincing explanation.

**The reactivity pattern of radicals is quite different from that of polar reagents**

The first reaction that you met in this book, in Chapter 6, was nucleophilic addition to a carbonyl group. Yet we have shown you no examples of radicals adding to carbonyl groups. This typical reaction of polar reagents is really quite rare with radicals. In Chapter 8 we introduced the concept of pKₐ in which we saw acids and bases exchanging protons. Among the strongest organic acids are those containing O–H bonds. Yet you have seen no radical reactions in which an O–H bond is broken. Carbon acids tend to be much weaker—yet you’ve seen plenty of examples of C–H bonds being broken by radical attack.

In Chapter 15 we introduced nucleophilic substitution at saturated carbon, using as an example some alkyl bromides. Now, radicals do react with alkyl halides—but not at carbon! Instead they abstract the halogen, leaving an alkyl radical.
The difference in reactivity between, say, organolithiums and radicals, both of them highly reactive, is nicely illustrated by the way in which they react with enones.

![1,4-addition](image)

We used the terms *hard* and *soft* in Chapters 15 and 22. From all these reactions it’s evident that radicals are very soft species: their reactions are driven not at all by the charge density on an atom but by the strength of the bonds being attacked and by the coefficients and energies of the frontier orbitals. O–H bonds are easily broken by strong bases and C=O bonds attacked by strong nucleophiles because of the polarization in the O–H and C=O bond. O–H and C=O bonds are strong, and radicals care nothing for polarization, so radicals prefer to attack the much weaker C–H bonds which (because they are unpolarized) are often inert towards ionic reagents.

**Summary of typical reactivity patterns**

**Alkyl radicals from boranes and oxygen**

Although the tin hydride + alkyl halide method is very efficient, tin compounds are falling out of favour because of their toxicity. The reaction between boranes and oxygen provides a simple alternative, and many of the reactions carried out formerly using the tin hydride radical chemistry of pp. 993–997 can now be done using the method we are about to describe.

Mixing trialkylboranes with α,β-unsaturated carbonyl compounds in the presence of water gives conjugate addition of one of the alkyl groups from the boron. The carbonyl compound can be an aldehyde (R² = H) or a ketone (R² = alkyl).

![image](image)

There was a dispute at first as to whether this was a radical reaction or an ionic reaction. The ionic reaction might have been a kind of pericyclic reaction with the intermediate boron enolate being hydrolysed by the water.
However, H. C. Brown discovered that the reaction was completely inhibited by just 5% of the stable radical galvinoxyl (shown on p. 975), known to be an efficient scavenger for radicals. But where were the radicals coming from? Further experiments showed that small amounts of oxygen were needed to make the reaction work. As you saw in Chapter 3, oxygen is a triplet diradical and displaces alkyl radicals from the trialkyl borane. This reaction looks at first like an \( S_N2 \) and is called an \( S_H2 \) (second order homolytic displacement), but in reality the oxygen adds to the empty p orbital of planar trigonal boron to release an alkyl radical and start the chain reaction.

\[
\begin{align*}
\text{R}_1 \text{B} & \quad \text{R}_1 \quad \text{OO} \\
& \quad \text{R}_1 \quad \text{B} \quad \text{R}_1
\end{align*}
\]

The alkyl radical now adds to the enone to give a delocalized intermediate that can be represented as a carbon- or oxygen-centred radical.

The chain is completed by displacement of another alkyl radical from a trialkylborane at oxygen by the delocalized radical and the formation of the same boron enolate proposed in the ionic reaction. This alkyl radical adds in its turn to the enone, and the boron enolate which forms is hydrolysed to the ketone product. Only small amounts of oxygen are needed to initiate the chain and it is not surprising that the air around the reaction mixture is enough to start a typical reaction. The water (which is inert to radicals, so can be present in the reaction mixture) again hydrolyses the boron enolate.

By combining a hydroboration step, which forms the borane, with the radical addition it is possible to carry out transformations such as the one below.

\[
\begin{align*}
\text{Ph} & \quad \text{Me}_3\text{SiO} \\
\text{Bu}_3\text{SnH} & \quad \text{Bu}_3\text{SnH} \\
\text{AIBN} & \quad \text{AIBN} \\
\text{THF, H}_2\text{O, 25 °C} & \quad \text{THF, H}_2\text{O, 25 °C}
\end{align*}
\]

85% yield

**Intramolecular radical reactions are more efficient than intermolecular ones**

All of the reactions you have met so far involve radical attack of one molecule on another. We’ve pointed out some of the drawbacks when C–C bonds are made in this way: the radical trap has to be activated (that is, electrophilic to capture nucleophilic radicals) and must often be present in excess, and the radical starting material must contain very weak C–X bonds (such as C–Br, C–I). The requirements are much less stringent, however, if the radical reaction is intramolecular. For example, this reaction works:

\[
\begin{align*}
\text{Me}_3\text{SiO} & \quad \text{Bu}_3\text{SnH} \\
\text{Bu}_3\text{SnH} & \quad \text{Bu}_3\text{SnH} \\
\text{AIBN} & \quad \text{AIBN} \\
\text{75% yield, mixture of diastereoisomers} & \quad \text{75% yield, mixture of diastereoisomers}
\end{align*}
\]
Notice that the double bond is not activated: in fact, it is nucleophilic, and the reaction still works even though the radical is also substituted with an electron-donating group. The C–S bond that is broken is also relatively strong, yet nonetheless a high yield of product is obtained. Why should this be so? What difference does it make that the reactions are intramolecular?

The key is that the intramolecular cyclization of the radical is now enormously favoured over other possible courses of action for the radical. Remember that when we were carrying out radical reactions intermolecularly, addition to the radical trap was encouraged by increasing the concentration of radical trap and decreasing the concentration of Bu3SnH to avoid radical reduction. For intramolecular reactions, the double bond that acts as the radical trap is always held close to the radical, and cyclization takes place extremely rapidly, even on to unactivated double bonds. The hydride donor (Bu3SnH) doesn’t get a look in, and can be present in higher concentrations than would otherwise be possible. Moreover, as there is only one equivalent of radical trap, and the trap need not be highly reactive, there is little danger of high concentrations of Bu3Sn• reacting with it, so the concentration of Bu3Sn• can build up to levels where the rate of abstraction of groups like Cl, SPh, and SePh is acceptable, despite their stronger C–X bonds.

For all these reasons, intramolecular radical reactions are very powerful, and are often used to make five-membered rings.

It is possible to make other ring sizes also, but the range is rather limited. Because of ring strain, three- and four-membered rings cannot be formed by radical reactions. Otherwise, smaller rings form faster than larger ones: look at these selectivities.
The preference for formation of a smaller ring is a very powerful one: in this reaction, the five-membered ring forms and not the six-membered one, even though cyclization to give a six-membered ring would also give a more stabilized radical.

We said earlier that the toxicity of tin poses some problems, so it is useful that the borane–oxygen method (p. 998) works well for initiating radical cyclizations too. It is not necessary to incorporate boron into the starting material, since a combination of Et₃B, O₂, and hypophosphorous acid, H₃PO₂, can generate a radical from a halide which will cyclize in the same way as the tin-promoted examples you have just seen. Once again, a five-membered ring is preferred to the alternative six-membered ring.

Notice that the ethyl groups from Et₃B are not incorporated into the product. The displacement of Et• from Et₃B initiates the chain reaction by abstracting the iodine atom from the starting material. The radical cyclizes to give a five-membered ring, as expected. A cis ring junction is inevitable because of the acetal ‘tether’.

The product radical has to collect a hydrogen from somewhere, and this is the role of the hypophosphorous acid. Abstraction of H gives a radical that can be drawn either as P-centred or O-centred.
The chain is finally completed by a hydrogen abstraction from $\text{H}_3\text{PO}_2$, which gives a radical that attacks the borane, just like oxygen did in the initiation step. A new ethyl radical is generated, which starts the cycle again.

![Diagram of radical reactions]

**Looking forward**

Radicals are important because they react in ways difficult to achieve with anions and cations, and show usefully different selectivity. Although radical reactions are generally less important than ionic reactions, environmental and biological radical reactions are remarkably common in an atmosphere that is 20% oxygen diradical. Diradicals will feature to a greater extent in the next chapter, in which we move on from carbon atoms carrying seven valence electrons to carbon atoms carrying only six valence electrons, called *carbenes*.

**Further reading**

The evidence that the McMurry reaction happens on a metal surface is quite nice, though, and if you’re interested you can read McMurry’s own account of it in *Accounts of Chemical Research*, 1983, 16, 405 and J. E. McMurry, *Chem. Rev.*, 1989, 89, 1513.

The borane-oxygen method of making radicals is reviewed by C. Ollivier and P. Renaud in *Chemical Reviews*, 2001, 101, 3415. In common with most *Chemical Reviews*, this is a long scholarly article but reviews like this are essential to chemists wanting to know about a new reagent, method, or synthesis.

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Synthesis and reactions of carbenes

Diazomethane makes methyl esters from carboxylic acids

In 1981, some chemists in Pennsylvania needed to convert this carboxylic acid into its methyl ester as part of the synthesis of an antibiotic compound. What reagent did they choose to do the reaction?

You remember, of course, that esters can be made from carboxylic acids and alcohols under acid catalysis, so you might expect them to use this type of method. On a small scale, it’s usually better to convert the acid to an acyl chloride before coupling with an alcohol, using pyridine (or DMAP) as a base; this type of reaction might have been a reasonable choice too.

But, in fact, they chose neither of these methods. Instead, they simply treated the carboxylic acid with a compound called diazomethane, CH₂N₂, and isolated the methyl ester.
Diazomethane, CH_2N_2, is a rather curious compound that has to be drawn as a dipole. There are several different ways of expressing its structure.

Diazomethane methylates carboxylic acids because carboxylic acids readily protonate it, giving an extremely unstable diazonium cation. This compound is desperate to lose N_2, the world’s best leaving group, and so it does, with the N_2 being substituted by the carboxylate anion. The carboxylate anion is in exactly the right position to carry out the S_N2 reaction shown below.

Diazomethane methylation is a good way of making methyl esters from carboxylic acids on a small scale because yields are excellent and the only by-product is nitrogen. However, there is a drawback: diazomethane has a boiling point of –24 °C, and it is a toxic and highly explosive gas. It therefore has to be used in solution, usually in ether; the solution must be dilute, because concentrated solutions of diazomethane are also explosive. It is usually produced by reaction of N-methyl-N-nitrosourea or N-methyl-N-nitrosotoluenesulfonamide with base, and distilled out of that reaction mixture as an azeotrope with ether, straight into a solution of the carboxylic acid.

Conveniently, solutions containing diazomethane are yellow, so the reaction is self-titrating—as the carboxylic acid reacts, the yellow diazomethane is removed, but as long as excess diazomethane remains the yellow colour persists.

The mechanism of the reaction that forms diazomethane is shown below. The key step is base-catalysed elimination, although the curly arrows we have to draw to represent this are rather tortuous!

Diazomethane will also methylate phenols because they too are acidic enough to protonate it. Ordinary alcohols, though, are not methylated because they are not strong enough acids to protonate diazomethane.
Selective methylation

Chemists studying the hormone degradation products present in the urine of pregnant women needed to methylate the phenolic hydroxyl group of the steroid oestriol. By using diazomethane, they avoided reaction at the two other hydroxyl groups. When, subsequently, they did want to methylate the other two hydroxyl groups, they had to add acid (HBF₄⁻) to the reaction to protonate the diazomethane.

![Chemical structures](image)

Photolysis of diazomethane produces a carbene

Alcohols can be methylated by diazomethane if the mixture is irradiated with light.

\[
\text{OH} + \text{CH}_2\text{N}_2 \xrightarrow{h\nu} \text{OMe} \quad \text{low yield}
\]

The mechanism is now totally different because the light energy promotes loss of nitrogen (N₂) from the molecule without protonation. This means that what is left behind is a carbon atom carrying just two hydrogen atoms (CH₂), and having only six electrons. Species like this are called carbenes, and they are the subject of this chapter.

![Mechanism diagram](image)

- Carbenes are neutral species containing a carbon atom with only six valence electrons.

The six electrons of a carbene are located two in each bond, plus two non-bonding electrons often represented as :CR₂ (as though they were a lone pair). As you will see later, this can be misleading, but :CR₂ is a widely used symbol for a carbene. In the case of :CH₂ generated from diazomethane, the carbene is trapped by the alcohol to make an ether.

Like the radicals in Chapter 37, carbenes are extremely reactive species. More important than their reaction with alcohols to make ethers are their reactions with alkenes to make cyclopropanes and their insertion into C–H bonds.

![Carbene reactions diagram](image)

- Typical carbene reactions

  The carbene inserts itself into a σ bond or a π bond.

  - Insertion in an O–H bond
  - Insertion in a C=C bond
  - Insertion in a C–H bond

We will discuss the mechanisms of these three important reactions shortly, but we have introduced them to you now because they demonstrate that the reactions of carbenes are dominated by insertion (here, insertion into O–H, C=C, and C–H) driven by their extreme...
electrophilicity. A carbon atom with only six electrons will do almost anything to get another two!

**How do we know that carbenes exist?**

The best evidence for the existence of carbenes comes from a group of structures which contain a carbene but are stable compounds. The most important of these are known as the ‘N-heterocyclic carbenes’—the carbene is incorporated into a five-membered ring and stabilized by the presence of two adjacent electron-donating nitrogen atoms and the bulky N-substituents. The example below was first made in 1991: it is crystalline, and its X-ray crystal shows the bond angle at the carbene carbon to be 102°, and 13C NMR confirms that the carbene C atom is electron deficient. We will come back to the significance of this later.

These stable carbenes are very much the exception: most carbenes are too reactive to be isolated. Reactive carbenes can, however, be observed by irradiating precursors (often diazo compounds like diazomethane, which we have just been discussing) trapped in frozen argon at very low temperatures (less than 77 K). IR and ESR spectroscopy (see p. 975) can then be used to determine their structure.

**Ways to make carbenes**

Carbenes are usually formed from precursors by the loss of small, stable molecules. We will discuss some of the most important methods in turn, but you have already seen one in action: the loss of nitrogen from a diazo compound.

**Carbenes from diazo compounds**

We showed you the formation of a carbene from diazomethane to illustrate how this reaction was different from the (ionic) methylation of carboxylic acids. But this is not a very practical way of generating carbenes, not least because of the explosive nature of diazalkanes. However, diazocarbonyl compounds are a different matter.

They are much more stable, because the electron-withdrawing carbonyl group stabilizes the diazo dipole, and are very useful sources of carbenes carrying a carbonyl substituent. There are two main ways of making diazocarbonyl compounds:

1. by reacting an acyl chloride with diazomethane

   ![Diazoalkane reaction](image)

   **Diazoalkane reaction**

2. by reacting the parent carbonyl compound with tosyl azide, TsN₃, in the presence of base.

   ![Tosyl azide reaction](image)

   **Tosyl azide reaction**
The reaction of diazomethane with acyl chlorides starts as a simple acylation to give a diazonium compound. If there is an excess of diazomethane, a second molecule acts as a base to remove a rather acidic proton between the carbonyl and the diazonium groups to give the diazocarbonyl compound.

\[ \text{RCl} + \text{H}_2\text{C}=\text{NN} \rightarrow \text{R} = \text{C} = \text{NO} + \text{MeCl} \]

What happens to that second molecule of diazomethane? By collecting a proton it turns into the very reactive diazonium salt, which collects a chloride ion, and MeCl is given off as a gas. The second method uses tosyl azide, which is just N\(_2\) attached to a good leaving group.

\[ \text{tosyl azide, TsN}_3 + \text{R} = \text{C} = \text{NO} \rightarrow \text{R} = \text{C} = \text{N} + \text{MeSO}_2\text{NH}_2 + \text{MeCl} \]

Diazocarbonyl compounds can be decomposed to carbenes by heat or light. The loss of gaseous nitrogen compensates energetically for the formation of the unstable carbene.

\[ \text{R} = \text{C} = \text{N} \rightarrow \text{R} = \text{C} + \text{N}_2 \]

It is much more common in modern chemistry to use a transition metal, such as copper or rhodium, to promote formation of the carbene.

\[ \text{RhL}_n \text{RC} = \text{N} \rightarrow \text{RH} = \text{C} + \text{N}_2 \]

Carbenes formed in this way are, in fact, not true carbenes because they remain complexed with the metal used to form them. They are known as carbenoids, and their reactions are discussed later in the chapter.

**Fischer carbenes**

While these rhodium and copper carbenoids are unstable, some transition metals such as tungsten and chromium form stable, isolable carbenoids, called metallocarbenes or Fischer carbenes.

\[ \text{Cr(CO)}_6 \quad \text{W(CO)}_5 \]

**Carbenes from tosylhydrazones**

Many more carbenes can be made safely from diazoalkanes if the diazoalkane is just an intermediate in the reaction and not the starting material. Good starting materials for these reactions are tosylhydrazones, which produce transient diazo compounds by base-catalysed elimination of toluenesulfinate. The diazo compound is not normally isolated, and decomposes to the carbene on heating.
Carbenes are formed in a number of other similar reactions—for example, loss of carbon monoxide from ketenes or elimination of nitrogen from azirines—but these are rarely used as a way of deliberately making carbenes.

**Carbene formation by α elimination**

In Chapter 17 we discussed β elimination in detail—reactions in which a hydrogen atom is removed from the carbon atom β to the leaving group. α Eliminations (eliminations in which both the proton and the leaving group are located on the same atom) are also possible—in fact, the reaction we've just been talking about (elimination of toluenesulfitinate from tosylhydrazones) is an α elimination. α Eliminations follow a mechanism akin to an E1cB β elimination—a strong base removes an acidic proton adjacent to an electron-withdrawing group to give a carbanion. Loss of a leaving group from the carbanion creates a carbene.

One of the best known α elimination reactions occurs when chloroform is treated with base. This is the most important way of making dichlorocarbene, :CCl₂, and other dihalocarbenes too, although it must be said that the widespread use of dichlorocarbene in chemistry is due mainly to the ease with which it can be made using this method!

Hydroxide and alkoxide anions are strong enough bases to promote α elimination from chloroform, and from other trihalomethanes. Carbenes can be formed from dihaloalkanes by deprotonation with stronger bases such as LDA, and even from primary alkyl chlorides using the extremely powerful bases phenylsodium or t-BuLi/t-BuOK (weaker bases just cause β elimination).

It is unfortunate that the term carbenoid is used for two distinct classes of molecule—usually it refers to the transition-metal bound carbene formed by metal-catalysed decomposition of diazo compounds (see p. 1018)—and for this reason the carbenoids that we are discussing here are best referred to as 'lithium carbenoids', with the metal specified.

When geminal dibromoalkanes are treated with BuLi, a halogen–metal exchange reaction produces a lithium carbenoid, with a metal atom and a halogen attached to the same carbon atom. Lithium carbenoids are stable at very low temperatures—they can be observed by NMR, but they decompose to carbenes at about −100 °C.
The essence of this type of carbenoid is that it should have a leaving group, such as a halogen, that can accept a pair of electrons and another, usually a metal, that can donate a pair of electrons. If the metal leaves first, a carbanion is created that can lose the halogen to make a carbene. They might also leave together. Both mechanisms are $\alpha$ eliminations.

While lithium carbenoids have limited applicability, an analogous zinc carbenoid, which can be formed by insertion of zinc into diiodomethane, is a reagent in one of the most widely used carbenoid reactions in chemistry—the Simmons–Smith reaction.

The problem with many of these reactions is that they require strong bases—either the organometallic compound itself is basic or a base must be used to create the carbanion. Carbenes are so unstable that they must be formed in the presence of the compound they are intended to react with, and this can be a problem if that compound is base-sensitive. For dichlorocarbene, a way round the problem is to make the carbanion by losing CO$_2$ instead of a metal or a proton. Decarboxylation of sodium trichloroacetate is ideal as it happens at about 80 °C in solution.

**Carbene formation by deprotonation of a cation**

Our final method is in some ways the most straightforward in terms of mechanism: simple removal of a proton from a stable cation. This is the method used to make very stable carbenes, and it works because both the cation used as the starting material and the carbene product are stabilized by one or more adjacent lone pairs. Here is an example. Imidazoles are nucleophilic, and can be alkylated to give relatively stable imidazolium cations, which we can represent with the charge delocalized between the two nitrogen atoms, although there is another possible representation with the charge on carbon.

When the imidazolium cation is treated with a strong base, for example sodium hydride, the proton of this central, partially positively charged carbon is removed, to give a compound which initially looks like a carbanion.
But we can use a curly arrow to move the negative charge towards the positively charged nitrogen, leaving a neutral species with a lone pair at carbon. A close look at the central carbon shows, however, that it has only two substituents—it is a carbene. Carbines with adjacent lone pairs can often be thought of in this way, the lone pair partially delocalized onto the C atom to help stabilize the electron-deficient carbene.

● Summary: the most important ways of making carbenes

Carbenes are neutral species containing a carbon atom with only six valence electrons.

Carbenes can be divided into two types

We made two important observations in the box on p. 1016 regarding the structure of carbenes that we will now return to and seek an explanation for. Firstly, we said that the X-ray crystal structure of the stable, crystalline carbene on the left shows that the bond angle at the carbene C is 102° and, secondly, we said that many carbenes can be observed by ESR—in other words, they have unpaired electrons.

Spectroscopic investigations of a number of carbenes of differing structures have shown that they fall broadly into two groups: (1) those (which you will learn to call ‘triplets’) that ESR spectroscopy demonstrates have unpaired electrons and whose bond angles are 130–150° and (2) those (like the stable crystalline carbene above, and which you will learn to call ‘singlets’) that have bond angles of 100–110° but cannot be observed by ESR. Many carbenes, like CH₂ itself, can be found in either group, although one may be more common.

All these observations can be accounted for by considering the electronic structure of a carbene. Carbines have two-coordinate carbon atoms: you might therefore expect them to have a linear (diagonal) structure—like that of an alkyne—with an sp hybridized carbon atom.
Such a linear carbene would have six electrons to distribute amongst two σ orbitals and two (higher-energy) p orbitals. The two electrons in the degenerate p orbitals would remain unpaired because of electron repulsion in the same way as in molecular oxygen •O–O•.

Yet few carbenes are linear: most are bent, with bond angles between 100° and 150°, suggesting a trigonal (sp$^2$) hybridization state. An sp$^2$ hybridized carbene would have three (lower-energy) sp$^2$ orbitals and one (high-energy) p orbital in which to distribute its six electrons. There are two ways of doing this. Either all of the electrons can be paired, with each pair occupying one of the sp$^2$ orbitals, or two of the electrons can remain unpaired, with one electron in each of the p orbitals and one of the sp$^2$ orbitals.

These two possibilities explain our two observed classes of carbene, and the two possible arrangements of electrons (spin states) are termed triplet and singlet. The orbitals are the same in both cases but in triplet carbenes we have one electron in each of two molecular orbitals and in singlet carbenes both electrons go into the sp$^2$ orbital.

Singlet and triplet carbenes

Triplet carbenes have two unpaired electrons, one in each of an sp and a p orbital, while singlet carbenes have a pair of electrons in a non-bonding sp$^2$ orbital and have an empty p orbital.
The existence of the two spin states explains the different behaviour of triplet and singlet carbenes towards ESR spectroscopy; the orbital occupancy also explains the smaller bond angle in singlet carbenes, which have an electron-repelling lone pair in an sp² orbital.

### Triplet carbenes

Two unpaired electrons: observable by ESR

Larger bond angle (130–150°)

Only one electron; less repulsion

### Singlet carbenes

No unpaired electrons: not observable by ESR

Smaller bond angle (100–110°)

Two electrons; more repulsion

In the table on p. 1010 we saw that the substituents on the carbene affect which of the two classes (which we now call singlet and triplet) it falls into. Why? All carbenes have the potential to exist in either the singlet or the triplet state, so what we mean when we say that a carbene such as :CH₂ is a ‘triplet carbene’ is that the triplet state for this carbene is lower in energy than the singlet state. The opposite is true for :CCl₂. Most type of carbenes are more stable as triplets because the energy to be gained by bringing the electron in the p orbital down into the sp² orbital is insufficient to overcome the repulsion that exists between two electrons in a single orbital.

For most triplet carbenes the singlet spin state that would arise by pairing up the two electrons lies only about 40 kJ mol⁻¹ above the ground (triplet) state: in other words, 40 kJ mol⁻¹ is required to pair up the two electrons.

Carbenes that have singlet ground states (such as :CCl₂) all have electron-rich substituents carrying lone pairs adjacent to the carbene centre. These lone pairs can interact with the p orbital of the carbene to produce a new, lower-energy orbital which the two electrons occupy. This stabilization of the lone pair provides the incentive that the electron in the p orbital needs to pair up in the sp² orbital.

This interaction corresponds to the point we made above about adjacent lone pairs stabilizing carbenes via the delocalization shown in the margin. As these arrows suggest, carbenes that have heavily electron-donating substituents are less electrophilic than other carbenes: indeed, diamino carbenes can be quite nucleophilic. The division of carbenes into two types explains...
their structure. It also helps to explain some of their reactions, especially those that have a stereochemical implication. We will spend the rest of this chapter discussing how carbenes react.

**The structure of carbenes depends on how they are made**

So far we have considered only the most stable possible structure, singlet or triplet, of a given carbene. In reality, a carbene will be formed in a chemical reaction and may well be formed as the less stable of the alternatives. If a reaction occurs by an ionic mechanism on a molecule with all electrons paired (as most molecules are!) then it must be formed as a singlet. Follow the α elimination mechanism, for example.

The starting material, a molecule of chloroform CHCl₃, has all paired electrons. The C–H σ bond breaks and the two paired electrons from it form the lone pair of the carbanion. The carbanion also has all paired electrons. The two paired electrons of one of the C–Cl bonds leaves the carbanion and the carbene is formed. It has two paired electrons in each of the two remaining C–Cl bonds and the lone pair, also paired. It is formed as a singlet. As it happens, the singlet version of CCl₂ is also the more stable. But if the carbene were instead CH₂ and if it reacted rapidly, it might not have a chance to change into the more stable triplet state. Since carbenes are very reactive, this question can be important. In explaining their reactions in the next section we shall need to consider:

- how the carbene was formed
- how rapidly it reacts
- whether it can change into the other state (singlet or triplet).

**How do carbenes react?**

Carbenes are desperate to find another pair of electrons with which to complete their valence shell of electrons. In this respect they are like carbocations. Like carbocations, they are electrophilic but, unlike carbocations, they are uncharged. This has consequences for the type of nucleophiles carbenes choose to react with. Carbocations attack nucleophiles with high charge density—those carrying a negative or partial negative charge (think of the type of nucleophiles that will take part in S₈ or Friedel–Crafts reactions). Carbenes, on the other hand, attack compounds we’d normally never consider as nucleophiles—even simple alkanes—by taking electrons from their HOMO. Of course, a carbocation will usually react with the HOMO of a molecule, but it will be much more selective about which HOMOs will do—usually these have to be lone pairs or electron-rich alkenes. For carbenes, any HOMO will do—a lone pair, a C=O double bond (electron-rich or -poor), or even a C–H bond.

As you will see (and as we generalized at the beginning of the chapter), many of these reactions can be considered as insertion reactions—overall the carbene appears to have found a bond and inserted itself in the middle of it. It’s important to remember that the term ‘insertion’ describes the overall consequence of the reaction, but isn’t always an accurate description of the reaction’s mechanism.

**Carbenes react with alkenes to give cyclopropanes**

This reaction is the most important way of making cyclopropanes, and is probably the most important reaction of carbenes. The mechanism of this type of reaction (an example is shown in the margin) depends on whether the carbene is a singlet or a triplet, and the outcome of the reaction can provide our first chemical test of the conclusions we came to in the
previous section. Singlet carbenes, like this one here (remember that substituents with lone pairs stabilize the singlet spin state) can add to alkenes in an entirely concerted manner: the curly arrows for the process can be written as shown in the margin.

Because the process is concerted, we expect that the geometry of the alkene should be preserved in the product—the reaction ought to be stereospecific. The two examples below show that this is indeed the case. It is more impressive that the Z alkene gives the cis-cyclopropane as this is less stable than the trans-cyclopropane and would change to E if it could.

The alkene insertion reaction is stereospecific only for singlet carbenes. For triplet carbenes, the reaction is non-stereospecific. In the example below, a triplet carbene gives a mixture of cyclopropane diastereoisomers from a pure Z alkene.

The mechanism of the reaction must be different with a triplet carbene. In fact, a concerted reaction is impossible for triplet carbenes because of the spins of the electrons involved. The spins of a triplet carbene aren’t paired, so once the carbene has added to the alkene in a radical reaction, the diradical (triplet) intermediate must wait until one of the spins inverts (‘flips’) before the second C–C bond can be formed with paired electrons.

Spin-flipping, which can occur only through collision with another molecule (of solvent usually), is relatively slow on the time-scale of molecular rotations and, by the time the electrons are in a fit state to pair up, the stereochemistry of the starting material has been scrambled by free rotation in the intermediate.
The same constraints arising from the need for conservation of electron spin apply to the formation as well as to the reaction of carbenes. When a carbene forms by α elimination, say, from a molecule with all electrons paired, it must be formed as the singlet, whether or not the triplet state is lower in energy. Only later may the carbene undergo spin-flipping to the triplet state. Since most carbene reactions are very rapid, this means that carbenes that are known to have triplet ground states may, in fact, react in their first-formed singlet state because they don’t have time to spin-flip to the triplet. This is true for :CH₂, produced from CH₂N₂, which adds stereospecifically to double bonds because it is formed as a singlet and because the singlet state is more reactive than the triplet.

**Some evidence for triplet carbenes in cyclopropane formation**

If the reaction is diluted with a large amount of an inert solvent such as C₃F₈ (perfluoropropane) then :CH₂ undergoes more collisions before it reacts and so the chances of spin-flipping of singlet :CH₂ to triplet :CH₂ is increased. Addition to alkenes is then less stereospecific.

![Interactive comparison of singlet and triplet carbenes in cyclopropane formation](image)

Stereospecificity (or lack of it) in the addition of a carbene to an alkene can be a good test of whether the carbene reacts as a singlet or triplet: lack of stereospecificity in a carbene addition almost certainly indicates that a triplet carbene is involved, but the fact that an addition is stereospecific doesn’t mean that the carbene must be a singlet. In some cases, bond rotation may be quite slow, and spin-flipping rapid, leading to stereospecific addition. Notice that in this example the less stable cis (Z) alkene was used: the reaction will give the less encumbered trans-cyclopropane if it can.

The addition of a triplet carbene to an alkene can be considered to be rather like a radical addition to a double bond. The concerted addition of a singlet carbene, on the other hand, is a pericyclic reaction, and from Chapter 34 you should be able to classify it as a [1 + 2] cycloaddition.

Addition of triplet carbenes is a radical reaction

Addition of singlet carbenes is a [1+2] cycloaddition

As a cycloaddition, singlet carbene addition to an alkene must obey the rules of orbital symmetry discussed in Chapters 34 and 35. We might consider the empty p orbital of the carbene (LUMO) interacting with the π bond (HOMO) of the alkene or the lone pair of the carbene in its filled sp² orbital (HOMO) interacting with the π* antibonding orbital of the alkene (LUMO).

![Interactive examples of other cheletropic reactions with SO₂](image)

You can immediately see that there is a problem when we try to interact these orbitals constructively to build two new bonds—direct approach of the carbene to the alkene is impossible because there is always an antibonding interaction. Two new bonds can be formed, however, if the carbene approaches the alkene in a ‘sideways-on’ manner.
The cyclopropane product must, of course, have a more or less tetrahedral arrangement about the carbon atom that was the carbene so that, even if the carbene approaches in a sideways-on manner, it must then swing round through 90° as the bonds form.

Making cyclopropanes

Many natural products and biologically active compounds contain cyclopropane rings: we shall feature just a few. First, a most important natural insecticide, a pyrethrin from the East African pyrethrum daisy, and its synthetic analogue decamethrin, one of the most important insecticides in agriculture. Very low doses of this highly active and non-persistent insecticide are needed.

The ‘ozone’ or ‘iodine’ smell of the sea has nothing to do with O₃ or I₂. It’s more likely a dictyopterene, a family of volatile cyclopropanes used by female brown algae to attract male gametes.

Other cyclopropanes include two natural but highly unusual amino acids. Hypoglycin is a blood sugar level lowering agent from the unripe fruit of the ackee tree. It’s the causative agent of Jamaican vomiting sickness. Don’t eat the green ackee.

The second and simpler amino acid is found in apples, pears, and grapefruit, and encourages fruit ripening by degradation to ethylene.

Our last and most extraordinary example is an antifungal antibiotic first synthesized in 1996 and containing no fewer than five cyclopropanes. It has the prosaic name FR-900848 but is known unofficially as ‘jawsamycin’.
Most chemical syntheses of compounds containing cyclopropyl groups make use of the addition of a carbene, or carbene equivalent, to an alkene. What do we mean by carbene equivalent? Usually, this is a molecule that has the potential to form a carbene, although it may not actually react via a carbene intermediate. One such example is the zinc carbenoid formed when diiodomethane reacts with zinc metal (most conveniently as a mixture with copper—a ‘zinc–copper couple’). It reacts with alkenes just as a carbene would—it undergoes addition to the π bond and produces a cyclopropane.

The reaction is known as the Simmons–Smith reaction, after the two chemists at the DuPont chemical factory who discovered it in 1958. Even after several decades, it is the most important way of making cyclopropane compounds, although nowadays a variant that uses more easily handled starting materials is often used. Diethyl zinc replaces the Zn/Cu couple of the traditional Simmons–Smith reaction. In this example, a double cyclopropanation on a C_2 symmetric diene derived from tartaric acid gives very good stereoselectivity for reasons we will soon discuss.

The mechanism of the Simmons–Smith reaction appears to be a carbene transfer from the metal to the alkene without any free carbene being released. It may look something like this.

Some of the evidence for this comes from a reaction that not only throws light on to the mechanism of Simmons–Smith cyclopropanations, but makes them of even greater value in synthesis. When an allylic alcohol is cyclopropanated, the new methylene group adds stereoselectively to the same face of the double bond as the hydroxyl group.

Allylic alcohols are also cyclopropanated over 100 times faster than their unfunctionalized alkene equivalents. Coordination between the zinc atom and the hydroxyl group in the transition state explains both the stereoselectivity and the rate increase. Unfortunately, while the Simmons–Smith reaction works well when a methylene (CH_2) group is being transferred, it is less good with substituted methylene groups (RCH: or R_2C:).

The carbene derived by metal-catalysed decomposition of ethyl diazoacetate attacks alkenes to introduce a two-carbon fragment into a cyclopropane—an industrial synthesis of ethyl chrysanthenate, a precursor to the pyrethrin insecticides (see p. 1016), uses this reaction. The diene in the starting material is more nucleophilic (has a higher energy HOMO; see Chapter 19) than the single alkene in the product, so the reaction can be stopped after one carbene addition.
The intramolecular version of this reaction is more reliable, and has often been used to make compounds containing multiply substituted cyclopropanes. Corey made use of it in a synthesis of sirenin, the sperm-attractant of a female water mould.

As you might imagine, carbenes like this, substituted with electron-withdrawing carbonyl groups, are even more powerful electrophiles than carbenes like :CCl₂, and will even add to the double bonds of benzene. The product is not stable, but immediately undergoes electrocyclic ring opening.

**Comparison of ‘-enoid’ reagents**

Before we leave this section on cyclopropanes, we want you to take a step back from simply thinking about carbenes, and consider the types of reagents that form three-membered rings generally. They all have something in common, which we could call ‘-enoid’ character. Cyclopropanes form when a carbene (which, in the singlet state, has an empty, electrophilic p orbital and a full, nominally nucleophilic sp² orbital) attacks alkenes. The Simmons–Smith carbenoid is not a carbene, but nonetheless has a carbon atom with joint nucleophilic (alkyl zinc) and electrophilic (alkyl iodide) character. When you think about it, the same is true for peracid epoxidation, which forms the oxygen analogue of a cyclopropane by attacking an alkene using an oxygen atom bearing both a lone pair (nucleophilic) and a carboxylate leaving group (electrophilic). It’s an ‘oxenoid’. In Chapter 27 you met other reagents that form cyclopropanes and epoxides by transferring CH₂—sulfonium ylids. These yet again have a carbon atom carrying both a negative charge and a leaving group. You can consider them to be particularly stable carbenoids.

**Insertion into C–H bonds**

We said that the formation of cyclopropanes by addition of substituted carbenes to alkenes was rare—in fact, alkyl-substituted carbenes undergo very few intermolecular reactions at all because they decompose very rapidly. When primary alkyl halides are treated with base, alkenes are formed by elimination. Having read Chapter 17, you should expect
the mechanism of this elimination to be E2 and, if you started with a deuterated compound like this, the alkene product would be labelled with two deuterium atoms at its terminus.

This is indeed what happens if the base is sodium methoxide ($pK_a[\text{MeOH}]$ about 16). If, however, it is phenylsodium ($pK_a[\text{benzene}]$ about 50), only 6% of the product is labelled in this way while 94% of the product has only one deuterium atom.

Evidently a hydrogen atom has ‘migrated’ from the 2-position to the 1-position. The overall mechanism of the elimination with very strong bases like phenylsodium is thought to be: (1) formation of a carbene by $\alpha$ elimination and then (2) 1,2-migration of a hydrogen atom on to the carbene centre. Carbones with $\beta$ hydrogens undergo extremely rapid 1,2-migration of hydrogen to the carbene centre, giving alkenes.

The reason for the rapid migration is that the electrophilic carbene has found a nearby source of electrons—the HOMO of the C–H bond—and it has grabbed the electrons for itself, ‘inserting’ into the C–H bond, as shown in the margin.

This type of reaction is better demonstrated by two examples in which the ‘insertion reaction’ is a bit more obvious: when there are no $\beta$ hydrogens, the carbene inserts into C–H bonds a little further away in the same molecule or even in the solvent (cyclohexane in the second example). In the first case, the carbene is formed by $\alpha$ elimination (using one of the ‘Schlosser bases’, see p. 1008) and, in the second case, by photolysis of a diazoketone.

Because these insertion reactions create new bonds at completely unfunctionalized centres, they can be very useful in synthesis. This next carbene is created between two carbonyl groups from a diazocompound with rhodium catalysis and selectively inserts into a C–H bond five atoms away to form a substituted cyclopentanone.
Pentalenolactone synthesis using carbenes

Pentalenolactone is the name given to an antibiotic extracted from Streptomyces fungi with an interesting tricyclic structure.

Two groups of chemists, within one year of each other, published syntheses of this compound using rhodium-promoted carbene insertions into C–H bonds. Cane’s insertion reaction (route 1) proceeds stereospecifically with retention of stereochemistry. This is excellent evidence for a concerted singlet carbene reaction. In Taber’s synthesis, the carbene inserts into the six-membered tetrahydropyran ring selectively to give the less strained 5,5-trans ring junction.

![route 1: Cane’s synthesis of pentalenolactone](image1)

![route 2: Taber’s synthesis of pentalenolactone](image2)

In these C–H insertion reactions, the similarity with cyclopropane formation by insertion into alkenes is clear, and the mechanisms mirror one another quite closely. As with the cyclopropanation reactions, the mechanism depends on whether the carbene is a singlet or triplet. Singlet carbenes can insert in a concerted manner, with the orbitals overlapping constructively provided the carbene approaches side-on.

![orbital interactions during the insertion of a singlet carbene into a C–H bond](image3)

This mechanism implies that, if the C–H bond is at a stereogenic centre, the stereochemistry at that centre will be retained through the reaction, as in Cane’s synthesis of pentalenolactone (see box above). A nice example of this result is this ingenious synthesis of α-cuparenone using a stereospecific carbene insertion.

![α-cuparenone](image4)

**Rearrangement reactions**

We talked just at the beginning of this section about migration reactions of hydrogen on to carbenes to give alkenes, and said that these reactions can be viewed as insertion reactions of...
carbenes into adjacent C–H bonds. Carbenes with no β hydrogens often insert into other C–H bonds in the molecule. However, carbenes with no β-hydrogen atoms can also undergo rearrangement reactions with alkyl or aryl groups migrating.

The most common example of this type of migration is that in which the carbene is adjacent to a carbonyl group. The initial product of what is known as the Wolff rearrangement is a ketene, which cannot be isolated but is hydrolysed to the acid in the work-up. Wolff rearrangement is a typical result of heating diazoketones, although as you saw above (p. 1019) these species also undergo intramolecular C–H insertion reactions.

One important application of this reaction is the chain extension of acyl chlorides to their homologous esters, known as the Arndt–Eistert reaction. Notice that the starting material for the Wolff rearrangement is easily made from RCO₂H by reaction of the acyl chloride with diazomethane; the product is RCH₂CO₂H—the carboxylic acid with one more carbon atom in the chain. A CH₂ group, marked in green, comes from diazomethane and is inserted into the C–C bond between R and the carbonyl group.

A synthesis of grandisol using the Arndt–Eistert chain extension

The boll weevil is a serious pest of cotton bushes, and it produces a sex pheromone known as grandisol. A common strategy for preventing insect damage in agriculture is to lure the weevils into a trap using synthetic versions of their own sex pheromones, and chemists soon showed that it was an easy matter to synthesize a related ester by a conjugate addition of an organocopper derivative (Chapter 22) and then alkylation of an ester enolate (Chapter 25). The enolate reacts with MeI on the face opposite the propenyl side chain—a good example of stereochemical control with cyclic compounds (Chapter 32).

This ester is one carbon atom short of the full side chain of grandisol, so an Arndt–Eistert reaction was used to lengthen the chain by one atom. First, the ester was converted into the diazoketone with diazomethane and then the Wolff rearrangement was initiated by formation of the carbene with a silver(II) salt.
Nitrenes are the nitrogen analogues of carbenes

The Wolff rearrangement has some important cousins that we must now introduce to you—they deserve a mention because they bear a family likeness even though they do not, in fact, involve carbenes. They are a group of reactions that proceed through an intermediate nitrene—the nitrogen analogue of a carbene. The simplest to understand, because it is the direct nitrogen analogue of the Wolff rearrangement, is the Curtius rearrangement. It starts with an acyl azide, which can be made by nucleophilic substitution on an acyl chloride by sodium azide. The acyl azide is what you would get if you just replaced the –CH=N=N_2 of a diazoketone with –N=N_2. And, if you heat it, it is not surprising that it decomposes to release nitrogen (N_2), forming the nitrene. The nitrene N has only one bond and has two lone pairs, making six electrons in all, like a carbene.

Nitrenes, like carbenes, are immensely reactive and electrophilic, and the same Wolff-style migration (insertion into an adjacent C–C bond) takes place in which the substituent R migrates from carbon to the electron-deficient nitrogen atom of the nitrene. The product is an isocyanate. Isocyanates are unstable to hydrolysis: attack by water on the carbonyl group gives a carbamic acid, which decomposes to an amine. Alternatively, reaction with an alcohol gives a carbamate. If the alcohol is BnOH, the product is a Cbz-protected amine.

Overall, then, the Curtius rearrangement converts an acid chloride (or an acid) to an amine with loss of a carbon atom—very useful. Also useful is the related Hofmann rearrangement, which turns an amide into an amine with loss of a carbon atom. This time we start with a primary amide and make a nitrene by treatment with base and bromine. Notice how close this nitrene-forming reaction is to the carbene-forming reactions we talked about on p. 1008. The nitrene rearranges just as in the Curtius reaction, giving an isocyanate that can be hydrolysed to the amine.
**Attack of carbenes on lone pairs**

Wolff rearrangements, involving shifts of alkyl groups, are effectively intramolecular insertions into C–C bonds. Carbenes will also insert into other bonds, especially O–H and N–H bonds, although the mechanism in these cases involves initial attack on the lone pair of the heteroatom.

Carbene attack is followed by proton transfer to generate a neutral molecule from the first formed zwitterion (or ‘ylid’). However, if the heteroatom does not carry a hydrogen, the ylid cannot rearrange in this way and this type of reaction is a very useful way of making reactive ylids that are inaccessible by other means.

As carbonyl-substituted carbenes (like carbonyl-substituted radicals) are electrophilic, their insertion into O–H and N–H bonds can be a useful way of making bonds in an umpolung (polarity-reversed, see Chapter 28) sense. Because of the difficulties in forming β-lactams (the four-membered rings found in the penicillin classes of antibiotics), the pharmaceutical company Merck decided to design a synthesis of the class of compounds known as carbapenems around a rhodium-catalysed carbene insertion into an N–H bond, building the five-membered ring on to the side of the four-membered ring.

**Alkene metathesis**

In this example, and in many before it, the formation of the carbene is initiated by a metal—often copper, rhodium, or silver. The carbene intermediates in these reactions are formed as reactive complexes with those metals, but in other cases the complexes are extremely stable. For example, decomposition of phenyldiazomethane in the presence of a ruthenium(II) complex gives a carbene complex stable enough to be isolated and stored for months. This complex, and a family of related Ru complexes, are among the most important of carbene-derived reagents because of a remarkable reaction known as alkene (or olefin) metathesis.

The reaction is most easily understood when a simple diene reacts with a very small amount (in this case 2 mol%) of the catalyst. A cyclization reaction occurs and the product is also an alkene. It contains no atoms from the catalyst: indeed, it has lost two carbon atoms, which are given off as ethylene.
What happens is a metathesis—an exchange of groups between the two arms of the molecule. But how? The mechanism is not difficult, but is unlike any other you have met before, except, perhaps, the Wittig reaction, which also forms alkenes. First, the carbene complex adds to one of the alkenes in what can be drawn as a \([2 + 2]\) cycloaddition (Chapter 34) to give a four-membered ring with the metal atom in the ring (a ‘metallacyclobutane’).

Now the same reaction happens in reverse, either unproductively to give back the starting materials or, by cleavage of the other two bonds, a new carbene complex and styrene.

This new complex has the same reactivity as the catalyst we started with, so it will quickly find another alkene to undergo \([2 + 2]\) cycloaddition with. There is now one in the same molecule, so a fast intramolecular reaction joins up the five-membered ring and produces a second metallacyclobutane. As before, there are two alternative ways for this metallacyclobutane to break down, and the productive one gives a third carbene complex and the cyclic product.

This new carbene complex is then ready to attack another molecule of starting material and the cycle is repeated, with the minor difference that ethylene (ethene) is now lost instead of styrene in the first step.

Not a lot can go wrong in this sequence, which is one reason why the yield is so high. Most of the steps are reversible, and the overall reaction is driven by the only irreversible step—the loss of ethylene as a gas. Even if the carbene complex adds the wrong way round to the alkene, nothing is lost because the only thing the resulting metallacycle can do is revert back to starting materials.
**Metathesis catalysts**

As you might imagine, the discovery of such a simple and efficient way of making new C=C bonds was a revolutionary point in organic chemistry, and earned a Nobel Prize in 2005 for the three chemists instrumental in its development—Yves Chauvin, Richard Schrock, and Robert Grubbs. The catalyst we have just been working with was developed by Grubbs and is often known by his name. The early years of the 21st century also saw a rapid improvement in the effectiveness of the catalysts used for metathesis. The most important development was the discovery of alternatives to the phosphine ligands, a change which increases the activity of the catalyst. The most important alternative ligands are themselves carbenes of the stable ‘N-heterocyclic’ type we introduced on p. 1006. Here is an important example, made by deprotonation of a heterocyclic cation:

There is a lot of delocalization in this structure, and usually these ligands are represented with a curved line to show the donation of both nitrogen lone pairs to the carbene C atom. You might prefer to include the formal + and – charges, but these compounds really do stretch the classical valence bond representation almost to breaking point, and conventionally the charges are not shown as they cancel out.

The remaining lone pair on carbon (which is not delocalized) can coordinate to Ru, just like the phosphine lone pair, giving a catalyst known as ‘Grubbs II’ (the ‘second generation’ of the ‘Grubbs I’ we made use of in the metathesis described above). In another widely used catalyst (known as the ‘Hoveyda–Grubbs catalyst’) the second phosphine is also replaced by intramolecular coordination.

**Cross metathesis**

The first metathesis we introduced you to is known, for obvious reasons, as a *ring closing metathesis* reaction, and the formation of rings—even of difficult ring sizes (see Chapters 16 and 31) is one of the supreme applications of metathesis chemistry. However, intermolecular metathesis reactions can also work under certain circumstances, especially when the coupling partners have very different electronic or steric properties. The challenge is of course avoiding each alkene coupling with itself. When one of the two partners is hindered and the other isn’t, the cross metathesis reaction works well: the four carbons of the two alkenes swap partners and a new alkene is produced (as its E isomer), along with ethylene as a by-product.
It’s not difficult to understand why the less reactive and more hindered alkene doesn’t react with itself, but why doesn’t the more reactive alkene just dimerize? The point is...it does! But it doesn’t matter because even the dimer is reactive as a metathesis substrate, and can still go on to form the product. All the metathesis steps proceed through the reversible [2+2] cycloaddition mechanisms you saw earlier.

Ene-yne metathesis

Before we leave metathesis, and carbenes, we need to introduce one final reaction where metathesis leads to a remarkable transformation. Metathesis works on any C=C π bond, but the π bonds need not be an alkene—it can be an alkyne. The scheme below shows what happens: the two C=C double bonds change places. When an alkene reacts with an alkene, the result is two new alkenes, but when an alkene reacts with an alkyne, there is still a single bond remaining from the original alkyne, which ends up linking the two products together as a diene.

The mechanism follows exactly the same sequence of events as before. First the ruthenium carbene catalyst undergoes [2+2] cycloaddition with the alkyne. The intermediate is now a metallacyclobutene, and when the reverse [2+2] takes place the Ru carbene is still connected to the alkene product.

Now the new carbene can undergo [2+2] cycloaddition and reverse [2+2] cycloaddition again, this time with the alkene component, and out comes the diene, plus a Ru carbene ready to start the cycle again.
Ene-yne metathesis is therefore a valuable way of constructing dienes—of the type you might require for a Diels–Alder reaction, for example. Unlike more reactive organometallics such as organolithiums and Grignard reagents, the Ru carbenes are fully compatible with acidic NH and OH bonds and with electrophilic carbonyl groups. You will meet more of the mild chemistry possible with organometallics in Chapter 40.

Summary

We have seen in this chapter how carbenes can be formed from many other reactive intermediates, such as carbocations, carbanions, and diazoalkanes, and how they can react to give yet further reactive intermediates such as ylids. Here is a summary of the main relationships between a carbene :CR₂ and these other compounds.

In the last few chapters we have concentrated a lot on what we call reactive intermediates, species like radicals, carbenes, or carbocations that are hard to observe but that definitely exist. Much of the evidence for their existence derives from the study of the mechanisms of reactions. We have discussed some aspects of this as we have met the species concerned, but in the next chapter we will look in detail at how mechanisms are elucidated and the methods used to determine more precisely the structure of reactive intermediates.

Determining reaction mechanisms

There are mechanisms and there are mechanisms

There are two types of answer to the question ‘What is the mechanism of this reaction?’ If you were asked to draw the mechanism of an ester hydrolysis in basic solution you should have no trouble in giving a good answer of the first type. It wouldn’t matter if you had never seen this particular ester before or even if you knew that it had never actually been made, because you would recognize that the reaction belonged to a class of well-known reactions (carbonyl substitution reactions, Chapter 10) and you would assume that the mechanism was the same as that for other ester hydrolysies. And you would be right—nucleophilic attack on the carbonyl group to form a tetrahedral intermediate is followed by loss of the alkoxide leaving group and formation of the anion of the carboxylic acid.

Yet someone at some time had to determine this mechanism in full detail. That work was done in the 1940s to 1960s and it was done so well that nobody seriously challenges it.
You might also recall from Chapter 12 that, if we change the carbonyl compound to an acid chloride, the mechanism may change to an S_N1 reaction with an acylium ion intermediate because the leaving group is now much better: Cl^- is more stable (less basic) than RO^-; it would not be worth using hydroxide for this reaction: as the first step is the slow step, water will do just as well. Again someone had to determine this mechanism, had to show which was the slow step, and had to show that leaving group ability depended on the pK_a of its conjugate base.

If the reaction were the hydrolysis of an amide, you might remember from Chapter 12 that third-order kinetics are often observed for the expulsion of such bad leaving groups and that this extra catalysis makes it worthwhile using concentrated base. Again, someone had to find out that: (1) the slow step is now the decomposition of the tetrahedral intermediate, (2) there are third-order kinetics involving two molecules of hydroxide, and (3) the first molecule acts as a nucleophile and the second as a base.

These three mechanisms are all versions of the same reaction. For you, writing these mechanisms chiefly means recognizing the type of reaction (nucleophilic substitution at the carbonyl group) and evaluating how good the leaving group is. For the original chemists, determining these reaction mechanisms meant: (1) determining exactly what the product is (that may sound silly, but it is a serious point), (2) discovering how many steps there are and the structures of the intermediates, (3) finding out which is the slow (rate-determining) step, and (4) finding any catalysis. This chapter describes the methods used in this kind of work—the detailed, second type of answer to ‘What is the mechanism of this reaction?’.

Now, suppose you were asked what the mechanisms of the next two reactions might be. This is a rather different sort of problem as you may well not recognize any of these reagents and you probably cannot fit any of the reactions into one of the classes you have seen so far. You may not even see at once which of the three main classes of mechanism you should use: ionic, pericyclic, or radical.

You may do your best to write a mechanism based on your understanding of organic chemistry, moving the electrons from nucleophiles to electrophiles, choosing sensible intermediates, and arriving at the right products. You would not claim any authority for the result, but you would hope, as an organic chemist, to propose one or more reasonable possibilities.

This process of proposing reasonable mechanisms is actually an essential preliminary to answering the question in the second way—finding the real, experimentally verified, mechanism for the reaction. We will now look at some of the techniques used to find such answers with an old curiosity of a reaction, the Cannizzaro reaction, as an example.
Determining reaction mechanisms: the Cannizzaro reaction

So how do we know the mechanism of a reaction? The simple answer is that we don’t for certain. Organic chemists have to face situations where the structure of a compound is initially thought to be one thing but later corrected to be something different. The same is true of mechanisms. It is the nature of science that all we can do is try to account for observations by proposing a hypothesis. We then test the hypothesis by experiment and, when the experiment does not fit the hypothesis, we must start again with a new hypothesis. This is exactly the case with mechanisms. When a new reaction is discovered, one or more mechanisms are proposed; evidence is then sought for and against these mechanisms until one emerges as the best choice. That one then remains the accepted mechanism for the reaction until fresh evidence comes along that does not fit the mechanism.

We are going to look at one reaction, the Cannizzaro reaction, and use this to introduce the different techniques used in elucidating mechanisms so that you will be able to appreciate the different information each experiment brings to light and how all the pieces fit together to leave us with a probable mechanism. Under strongly basic conditions, an aldehyde with no α hydrogens undergoes disproportionation to give half alcohol and half carboxylate. Disproportionation means one half of the sample is oxidized by the other half, which is itself reduced. In this case, half the aldehyde reduces the other half to the primary alcohol and in the process is oxidized to the carboxylic acid. Before the discovery of LiAlH₄ in 1946, this was one of the few reliable ways to reduce aldehydes and so was of some use in synthesis.

Here is a simple mechanistic scheme of what happens—the sort of thing you might reasonably propose if you had not seen the reaction before.

\[ R\text{-CHO} + \text{HO}^- \rightarrow R\text{-CH(OH)OH} \rightarrow R\text{-CO}^- + \text{HO}^- + H^+ \]

It’s not the only possible mechanism by any means—and you may spot that it is slightly different from the one in Chapter 26, where we showed a dianion as an intermediate. We’ll now work through some of the alternative mechanisms that have been proposed for the Cannizzaro reaction, along with the evidence for or against them. Most of these alternatives have been eliminated, leaving just the ones you have already met. Finally, we will see that even these mechanisms do not explain everything absolutely.

Proposed mechanism A: a radical mechanism

Early on it was thought that the hydrogen transfer might be taking place via a radical chain reaction. If this were the case, then the reaction should go faster if radical initiators are added and it should slow down when radical inhibitors are added. When this was tried, there was no change in the rate, so this proposed mechanism was ruled out.

Kinetic evidence for an ionic mechanism

The first piece of evidence that must be accounted for is the rate law. For the reaction of benzaldehyde with hydroxide, the reaction is first order with respect to hydroxide ions and second order with respect to benzaldehyde (third order overall).

\[ \text{rate} = k_4[\text{PhCHO}]^2[\text{HO}^-] \]

For some aldehydes, such as formaldehyde and furfural, the order with respect to the concentration of hydroxide varies between one and two depending on the exact conditions. In high concentrations of base it is fourth order.

\[ \text{rate} = k_4[\text{RCHO}]^2[\text{HO}^-]^2 \]
At lower concentrations of base the rate law is a mixture of both third- and fourth-order terms.

\[
\text{rate} = k_3[RCHO]^2[\text{HO}^-] + k_4[RCHO]^2[\text{HO}^-]^2
\]

Just because the overall order of reaction is third or fourth order, it does not mean that all the species must simultaneously collide in the rate-determining step. You saw in Chapter 12 that the rate law actually reveals all the species that are involved up to and including the rate-determining step.

**Isotopic labelling**

When the reaction is carried out in D\(_2\)O instead of in H\(_2\)O it is found that there are no C—D bonds in the products. This tells us that the hydrogen must come from the aldehyde and not from the solvent.

**Proposed mechanism B: formation of an intermediate dimeric adduct**

A possible mechanism that fits all the experimental evidence so far involves nucleophilic attack of the usual tetrahedral intermediate on another aldehyde to give an intermediate adduct. This adduct could then form the products directly by hydride transfer. You may not like the look of this last step, but the mechanism was proposed and evidence is needed to disprove it.

Which step would be rate determining for this mechanism? It could not be step 1 since, if this were the case, the rate law would be first order with respect to the aldehyde rather than the observed second-order relationship. Also, if the reaction is carried out in water labelled with oxygen-18, the oxygen in the benzaldehyde exchanges with the \(^{18}\text{O}\) from the solvent much faster than the Cannizzaro reaction takes place. This can only be because of a rapid equilibrium in step 1 and so step 1 cannot be rate determining.

So, for mechanism B, either step 2 or step 3 could be rate determining—either case would fit the observed rate law. Step 2 is similar to step 1: in both cases an oxyanion nucleophile attacks the aldehyde. Since the equilibrium in step 1 is very rapid, it is reasonable to suggest that the equilibrium in step 2 should also be rapid and thus that the hydride transfer in step 3 must be rate determining. So mechanism B can fit the rate equation.

How can mechanism B be ruled out? One way is to change the attacking nucleophile. The Cannizzaro reaction works equally well if methoxide is used in a mixture of methanol and water. If mechanism B were correct, the reaction with methoxide would be as follows.
One of the products would be different by this mechanism: benzyl methyl ether would be formed instead of benzyl alcohol. None is observed experimentally. Moreover, under the conditions of the experiment, benzyl methyl ether does not react to form benzyl alcohol, so it cannot be the case that the ether is formed but then reacts to form the products. Mechanism B can therefore be ruled out.

**Proposed mechanism C: formation of an ester intermediate**

This mechanism is like mechanism B but the hydride transfer in the adduct formed in step 2 displaces OH\(^-\) to form an ester (benzyl benzoate) that is then hydrolysed to the products. This was at one time held to be the correct mechanism for the Cannizzaro reaction. One piece of evidence for this, and at first glance a very good one, is that by cooling the reaction mixture and avoiding excess alkali, some benzyl benzoate could be isolated during the reaction. An important point is that this does not mean that the ester must be an *intermediate* in the reaction—it might be formed at the end of the reaction, for example. However, it does mean that any mechanism we propose must be able to account for its formation. For now though we want to try to establish whether the ester is an intermediate rather than a by-product in the Cannizzaro reaction.

An early objection to mechanism C was that the ester would not be hydrolysed fast enough. When someone actually tried it under the conditions of the experiment, they found that benzyl benzoate is very rapidly hydrolysed (the moral here is ‘don’t just think about it, try it!’). However, just because the ester *could be* hydrolysed, it still did not show that it actually was an intermediate in the reaction. How this was eventually shown was rather clever. The argument goes like this. We can measure the rate constant for step 4 by seeing how quickly pure benzyl benzoate is hydrolysed to benzyl alcohol and benzoate under the same conditions as those of the Cannizzaro reaction. We also know how quickly these products are formed during the Cannizzaro reaction itself. Since, if this mechanism is correct, the only way the products are formed is from this intermediate, it is possible to work out how much of the intermediate ester must be present at any time to give the observed rate of formation of the products. If we can measure the amount of ester that is actually present and it is significantly less than that which we predict, then this cannot be the correct mechanism. It turned out that there was never enough ester present to account for the formation of the products in the Cannizzaro reaction and mechanism C could be ruled out.

**The correct mechanism for the Cannizzaro reaction**

The only mechanism that has not been ruled out and that appears to fit all the evidence is the one we have already given (p. 1031). The fact that the rate law for this mechanism is overall third and sometimes fourth order depending on the aldehyde and the conditions can be explained by the involvement of a second hydroxide ion deprotonating the tetrahedral intermediate to give a dianion. When methoxide is used in a methanol/water mix, some methyl ester is formed. This does not stay around for long—under the conditions of the experiment it is quickly hydrolysed to the carboxylate.
Even this mechanism does not quite fit all the evidence

We said earlier that we can never prove a mechanism—only disprove it. Unfortunately, just as the ‘correct’ mechanism seems to be found, there are some observations that make us doubt this mechanism. In Chapter 37 you saw how a technique called electron spin resonance (ESR) (or electron paramagnetic resonance, EPR) detects radicals and gives some information about their structure. When the Cannizzaro reaction was carried out with benzaldehyde and a number of substituted benzaldehydes in an ESR spectrometer, a radical was detected. For each aldehyde used, the ESR spectrum proved to be identical to that formed when the aldehyde was reduced using sodium metal. The radical formed was the radical anion of the aldehyde.

Our mechanism does not explain this result, but small amounts of radicals are formed in many reactions in which the products are actually formed by simple ionic processes. Detection of a species in a reaction mixture does not prove that it is an intermediate. Few chemists think that radicals are involved in the Cannizzaro reaction. Most think the mechanism we have given is correct.

Variation in the structure of the aldehyde

Before leaving the Cannizzaro reaction, look at these rates of reactions for aromatic aldehydes with different substituents in the para position. These aldehydes may be divided into two classes: those that react faster than unsubstituted benzaldehyde and those that react more slowly. Those that go slower all have something in common—they all have substituents on the ring that donate electrons.

We have already seen how substituents on a benzene ring affect the rate of electrophilic substitution (Chapter 21). Electron-donating groups such as MeO and Me₂N dramatically speed up the rate at which an aromatic ring is attacked by an electrophile, whereas electron-withdrawing groups, particularly nitro groups, slow the reaction down. The Cannizzaro reaction is not taking place on the benzene ring itself, but substituents on the ring still make their presence known. The fact that the Cannizzaro reaction goes much slower with electron-donating groups and faster with electron-withdrawing groups tells us that, for this reaction, rather than a positive charge developing, as in the case of electrophilic substitution on an aromatic ring, there must be negative charge accumulating somewhere near the ring. The accumulation of more negative charge is disfavoured by the presence of a group that is already offloading electron density into the ring. In agreement with this, our mechanism has mono- and dianion intermediates, which are stabilized by electron-withdrawing groups and destabilized by electron-donating groups.
The rest of the chapter is devoted to discussions of methods similar to those we have briefly surveyed for the Cannizzaro reaction, with examples of the use of each method. You can assume that the mechanisms we have discussed in this book have been verified (not, of course, proved) by these sorts of methods.

**Be sure of the structure of the product**

This seems a rather obvious point. However, there is a lot to be learned from the detailed structure of the product: its connectivity (which atom goes where) as well as its stereochemistry. You will see that it may be necessary to alter the structure of the starting material in subtle ways to make sure that we know exactly what happens to all its atoms by the time it reaches the product.

Suppose you are studying the addition of HCl to this alkene. You find that you get a good yield of a single adduct and you might be a bit surprised that you do not get a mixture of the two obvious adducts. You may wonder if there is some participation of the ether oxygen or whether perhaps the ketone enolizes during the reaction and controls the outcome.

![Diagram](image)

If you are cautious you might check on the structure of the product before you start a mechanistic investigation. The NMR spectrum (above) tells you at once that the product is neither of these suggestions. It contains a \((\text{CH}_2)_3\text{Cl}\) unit and can no longer have an eight-membered ring. A ring contraction has given a five-membered ring and a mechanistic investigation is hardly needed. Simply knowing what the product is allows us to propose a mechanism. A rearrangement has occurred and we could use the method suggested in Chapter 36: number the atoms in the starting material and find them in the product. This is quite easy as only one numbering system makes any sense.

![Diagram](image)

This numbering suggests that the carbon skeleton is unaffected by the reaction, that protonation has occurred at C5, that the ether oxygen has acted as an internal nucleophile across the ring at C4, and that the chloride ion has attacked C7. The mechanism is straightforward.
It may be disappointing to find that every step in this mechanism is well known and that the reaction is exactly what we ought to have expected with an eight-membered ring as these rings are famous for their transannular (across-ring) reactions to form 5/5 fused systems. However, it is good that a prolonged investigation is not necessary.

- Find out for sure what the structure of the product is before you start a mechanistic investigation.

A more subtle distinction occurred in a study of the bromination of alkynes. Bromination of benzyl alkynes in acetic acid gave the products of addition of one molecule of bromine—the 1,2-dibromoalkenes. The reaction was successful with a variety of para substituents and there seems at first to be no special interest in the structure of the products.

Closer investigation revealed an extraordinary difference between them, not at all obvious from their NMR spectra: the compound from X=OMe was the Z-dibromoalkene from cis addition of bromine while the product from X=CF3 was the E alkene from trans addition. What mechanism could explain this difference?

The anti addition is more easily explained: it is the result of formation of a bromonium ion, similar, in fact, to the normal mechanism for the bromination of alkenes. Bromine adds from one side of the alkene and the bromide ion must necessarily form the E-dibromo product regardless of which atom it attacks.

So why does the p-methoxy-substituted compound behave differently? It cannot react by the same mechanism and a reasonable explanation is that the much more electron-donating ring participates in the reaction to give a carbocyclic three-membered ring intermediate that is attacked in an anti fashion to give the Z alkene. Both intermediates are three-membered ring cations and both are attacked with inversion but the p-MeO compound undergoes double inversion by participation of the ring.

A similar aryl participation in saturated compounds, giving a ‘phenonium ion’ intermediate, appears in Chapter 36, p. 936.
Labelling experiments reveal the fate of individual atoms

It often happens that the atoms in starting material and product cannot be correlated without at least one of them being labelled. The fact that many elements exist as different isotopes provides us with a perfect way of doing this: a neutron more or less in the nucleus affects the physics (and hence the spectroscopic features) of an atom, but not its chemistry.

The isomerization of Z-1-phenylbutadiene to the E diene in acid looks like a simple reaction. Protonation of the Z alkene would give a stabilized secondary benzylic cation that should last long enough to rotate. Loss of the proton would then give the more stable E diene.

However, reaction with D⁺ in D₂O reveals that this mechanism is incorrect. The product contains substantial amounts of deuterium at C4, not at C2 as predicted by the proposed mechanism. Protonation must occur at the end of the conjugated system to produce the more stable conjugated cation, which rotates about the same bond and loses H or D from C4 to give the product. More H than D will be lost, partly because there are two Hs and only one D, but also because of the kinetic isotope effect, of which more later.

The easiest labels to use for this job are D for H, ¹³C, and ¹⁸O. None of these is radioactive; all can be found by mass spectrometry, while D and ¹³C can be found by NMR. Older work on mechanisms used radioactive tracers such as T (tritium, ³H) for H and ¹⁴C.

The first evidence for benzyne as the intermediate in the reaction of chlorobenzene with NH₂⁻ came from radioactive labelling. If benzyne is an intermediate, the product should have 50% label at C1 and 50% at the two identical ortho carbons, as the scheme below shows.

The labelled aniline was degraded by the reactions shown here, which you must agree was a lot of work for the chemists concerned. Each potentially labelled carbon atom had to be isolated from any other labelled atom and the radioactivity measured. We shall follow the fate of the two labelled atoms with black and green spots. Since the two ortho positions are identical, we must put a black spot on both of them.

Most of these reactions are well known—the Beckmann rearrangement is described in Chapter 36 and the Curtius reaction in Chapter 38—but the oxidation of the diamine to the
dicarboxylic acid is not a standard procedure and is not recommended. All the label came out in the CO₂ and almost exactly half of it was from the black and half from the green labelled carbons. This was the original evidence that convinced organic chemists in 1953 that benzyne was involved in the reaction. The evidence presented in Chapter 22 is much more modern.

**The value of double labelling experiments**

An altogether more modern approach to a labelling study was used in the surprising rearrangement of a hydroxy-acid in acidic solution. The structure of the product suggests a CO₂H migration as the most likely mechanism. This mechanism resembles closely the cationic rearrangements of Chapter 36.

![CO₂H migration](image)

But there are other possibilities: received wisdom (Chapter 36) suggests that the best migrating group in cationic rearrangements is the one best able to bear a positive charge, by which logic the more familiar Ph and Me migrations ought to be preferred. A more elaborate mechanism can be written: it involves two methyl migrations and one phenyl migration and it also needs consideration.

![Alternative mechanisms](image)

These mechanisms can be tested by finding out whether the CO₂H group remains attached to its original position or becomes attached to the other carbon in the skeleton of the molecule. This can be done by double labelling. If a compound is prepared with two ¹³C labels, one on the CO₂H group itself and one on the benzylic carbon, the NMR spectrum of the product will show what has happened. In fact, the two ¹³C labels end up next to each other with a coupling constant \( J_{CC} = 71 \text{ Hz} \). It is the CO₂H group that has migrated.

So why does the CO₂H group migrate? It does so not because it is a good migrating group, but because it cannot bear to be left behind. The rearranged cation from CO₂H migration is a stable tertiary alkyl cation. The cation from Me migration is a very unstable cation, with the positive charge next to the CO₂H group. Such cations are unknown as the carbonyl group is very electron withdrawing.

**‘Crossover’ experiments**

There is still one tiny doubt. Supposing the reaction is not intramolecular at all, but intermolecular. The CO₂H group might be lost from one molecule as protonated CO₂ and be picked up by another molecule of alkene. No migration would be involved at all.
This mechanism can be checked by using a 50:50 mixture of doubly labelled and unlabelled starting material. The molecule of alkene that captures the roving protonated labelled CO$_2$ might happen to be labelled too but equally well it might be unlabelled. If this last mechanism is correct, we should get a mixture of unlabelled, singly labelled, and doubly labelled product in the ratio 1:2:1 as there are two types of singly labelled product. The two singly labelled compounds are called the crossover products and the experiment is called a crossover experiment as it discovers whether any parts of one molecule cross over to another.

In fact, no singly labelled compounds were found: NMR analysis showed that the product consisted entirely of unlabelled or doubly labelled molecules. The CO$_2$H group remains attached to the same molecule (though not to the same atom) and the first mechanism is correct.

Crossover experiments demand some sort of double labelling, which does not have to be isotopic. An example where crossover products are observed is the light-initiated isomerization of allylic sulfides.

This is formally a [1,3] sigmatropic shift of sulfur (Chapter 35) but that is an unlikely mechanism (and you should be able to suggest why). A crossover experiment was carried out in which the two molecules had either two phenyl groups or two para-tolyl groups. The mixture was allowed to rearrange in daylight and the products were examined by mass spectroscopy. There was a roughly 1:2:1 mixture of products having two phenyl groups, one phenyl and one para-tolyl group, and two para-tolyl groups. The diagram shows the starting materials and the two crossover products only.

Clearly, the ArS group had become separated from the rest of the molecule and the most likely explanation was a radical chain reaction (Chapter 37) with the light producing a small amount of ArS$^*$ to initiate the chain. The para-methyl group acts as a label. The whole system is in equilibrium and the more highly substituted alkene is the product.
Systematic structural variation

In this last example, the hope is that the para-methyl group will have too weak an electronic or steric effect and in any case will be too far away to affect the outcome. It is intended to make nearly as slight a change in the structure as an isotopic label. Many structural investigations have exactly the opposite hope. Some systematic change is made in the structure of the molecule in the expectation of a predictable change in rate. A faster or slower reaction will lead to some definite conclusion about the charge distribution in the transition state.

Allylic compounds can react efficiently with nucleophiles by either the $S_N1$ or $S_N2$ mechanisms (Chapter 15). Here are two examples.

\[
\text{OMs} \overset{\text{H}_2\text{O}}{\longrightarrow} \text{OH} \quad \text{OMs} \overset{\text{Nal}}{\longrightarrow} \text{I}
\]

The carbon skeleton is the same in both reactions but the leaving groups and the nucleophiles are different. These reactions might both go by $S_N1$ or $S_N2$ or one might go by $S_N1$ and the other by $S_N2$. One way to find out is to make a large change in the electronic nature of the carbon skeleton and see what happens to the rate of each reaction. In these experiments one of the methyl groups was changed for a CF$_3$ group—exchanging a weakly electron-donating group for a strongly electron-withdrawing group. If a cation is an intermediate, as in the $S_N1$ reaction, the fluorinated compound will react much more slowly. Here is the result in the first case.

\[
\text{OMs} \overset{\text{H}_2\text{O}}{\longrightarrow} \text{OH} \quad \text{OMs} \overset{\text{F}_3\text{C}}{\longrightarrow} \text{OH}
\]

The fluorinated compound reacts half a million times more slowly so this looks very much like an $S_N1$ mechanism. The slow step in an $S_N1$ mechanism is the formation of a carbocation so any group that destabilizes the positive charge would have (and evidently does have) a large effect on the rate. Rate ratios of several powers of ten often are worth noticing and a rate ratio of nearly $10^6$ is considerable. In the second case the rate difference is much less.

\[
\text{Cl} \overset{\text{Nal}}{\longrightarrow} \text{I} \quad \text{F}_3\text{C} \text{Cl} \overset{\text{Nal}}{\longrightarrow} \text{I}
\]

A rate ratio of 11 is not worth noticing. The point is not that the fluorinated compound reacts faster but that the two compounds react at about the same rate. This strongly suggests that no charge is generated in the transition state and an $S_N1$ mechanism is not happening. The $S_N2$ mechanism makes good sense with its concerted bond formation and bond breaking requiring no charge on the carbon skeleton.

\[
\text{OMs} \overset{\text{H}_2\text{O}}{\longrightarrow} \text{OH} \quad \text{OMs} \overset{\text{F}_3\text{C}}{\longrightarrow} \text{OH}
\]

The CF$_3$ group works well here as a mechanistic probe because it is held well out of the way of the reaction site by a rigid $\pi$ system but is connected electronically by that same allylic system. Steric effects should be minimized and electronic effects clearly seen. This approach is clearly limited by the small number of groups having properties like those of the CF$_3$ group and the small number of reactions having such favourable carbon skeletons. We will now present the most important serious correlation between structure and reactivity.
The Hammett relationship

What we would ideally like to do is find a way to quantify the effects that electron-donating or -withdrawing groups have on the transition state or intermediate during the course of a reaction. This will then give us an idea of what the transition state is really like. The first question is: can we define exactly how efficient a given group is at donating or withdrawing electrons? Hammett took the arbitrary decision to use the pKₐ of an acid as a guide. For example, the rate of hydrolysis of esters might well correlate with the pKₐ of the corresponding acid.

When Hammett plotted the rates of ethyl ester hydrolyses (as log k since pKₐ has a log scale) against the pKₐs of the corresponding acids, the initial results were not very encouraging as there was a random scatter of points over the whole graph.

Hammett had used some aliphatic acids (substituted acetic acids) and some aromatic acids (substituted benzoic acids) and he noticed that many of the points towards the top of the graph belonged to the substituted acetic acids. Removing them (brown points) made the graph a lot better. He then noticed that the remaining aromatic compounds were in two classes: the ortho-substituted esters reacted more slowly than their meta- and para-isomers and came towards the bottom of the graph (orange points). Removing them made the graph quite good (remaining green points).

It was not a perfect correlation but Hammett had removed the examples where steric hindrance was important. Aliphatic compounds can adopt a variety of conformations (Chapter 16) and the substituent in some of them will interfere with the reaction. Similarly, in ortho-substituted aromatic compounds the nearby substituent might exert steric hindrance on the reaction. Only with meta- and para-substituted compounds was the substituent held out of the way, on a rigid framework, and in electronic communication with the reaction site through the flat but conjugated benzene ring.

Notice that the straight line is not perfect. This graph is an invention of the human mind. It is a correlation between things that are not directly related. If you determine a rate constant by plotting the right function of concentration against time and get an imperfect straight line, that is your fault because you haven’t done your measurements carefully enough. If you make a Hammett plot and the points are not on a straight line (and they won’t be) then that is not your fault. The points really don’t fit on a perfectly straight line. As you will see soon, this doesn’t actually matter.
The Hammett substituent constant $\sigma$

A quick glance at the $pK_a$s of some substituted benzoic acids in the table below will show how well they correlate electron donation with $pK_a$. The substituents at the top of the table are electron donating and the anions of the benzoic acids are correspondingly less stable so these are the weakest acids. At the bottom of the table we have the electron-withdrawing groups, which stabilize the anion and make the acid stronger. The whole range is not that great, only one pH unit or so, because the carboxylate anion is not conjugated with the ring.

Hammett decided not to use the $pK_a$s themselves for his correlation but defined a new parameter, which he called $\sigma$. This $\sigma$ shows how electron donating or withdrawing a group is relative to H as a difference between the $pK_a$s of a benzoic acid derivative with the substituent and benzoic acid itself. If the acid required to determine $\sigma$ for a new substituent was not available, $\sigma$ could be determined by correlation with other reactions. Here are the equations and the table of $\sigma$ values for the most important substituents. A different value of $\sigma$ for any given substituent was needed for the meta and the para positions and these are called $\sigma_m$ and $\sigma_p$, respectively.

$$\sigma_X = \log \left( \frac{K_a(XC_6H_4COOH)}{K_a(C_6H_5COOH)} \right) = pK_a(C_6H_5COOH) - pK_a(XC_6H_4COOH)$$

</table>

There is no point learning the precise figures in this table, but it will help if you form a general idea of what a $\sigma$ value means. If $\sigma = 0$ the substituent has no effect: it is electronically the same as H. If $\sigma$ is positive, the substituent is electron withdrawing. This is unfortunate perhaps, but just remember that the comparison is with acid strength, and acids with electron-withdrawing substituents are stronger. Positive $\sigma$ means a stronger acid so the substituent is electron withdrawing. The more positive the charge induced on the ring by a substituent, the larger its $\sigma$ value. Negative $\sigma$ means weaker acid and electron donation. Inductive effects from polarization of $\sigma$ bonds are greater for $\sigma_m$ than for $\sigma_p$ because the substituent is nearer.
Conjugation is generally more effective in the para position (see Chapter 21) so \( \sigma_p > \sigma_m \) for conjugating substituents. Indeed, the \( \text{NH}_2 \) group has a large negative \( \sigma_p \) and a zero \( \sigma_m \). The \( \text{NH}_2 \) group donates electrons strongly to the carbonyl group of benzoic acid from the para position but does not conjugate in the meta position where its donation happens just to balance the effect of electronegative nitrogen.

The OMe group has a negative \( \sigma_p \) but a positive \( \sigma_m \) because a weaker electron donation from the lone pairs is more important in the para position but the effect of very electronegative oxygen on the \( \sigma \) framework of the ring in the meta position is more important than lone pair donation that doesn’t reach the carbonyl group. You do not need to learn any \( \sigma \) values but you should be able to work out the sign of \( \sigma \) for well-known substituents and estimate a rough value.

The Hammett reaction constant \( \rho \)

Now we can return to our reaction: the alkaline hydrolysis of various meta- and para-substituted ethyl benzoates. We sketched the graph earlier (p. 1041) but now we can add some more quantitative detail. The rate constants for this second-order reaction have been measured and shown here is a graph of \( \log (k_X/k_H) \) versus \( \sigma \), where \( k_X \) is the rate constant for the reaction with the substituted benzoate and \( k_H \) is that for the unsubstituted reaction (\( X=\text{H} \)).

We can see straight away that there is a good correlation between how fast the reaction goes and the value of \( \sigma \); in other words, the points lie more or less on a straight line. The gradient of this best-fit line, given the symbol \( \rho \) (rho), tells us how sensitive the reaction is to substituent effects in comparison with the ionization of benzoic acids. The gradient is \( \rho = 2.6 \). This tells us that the reaction responds to substituent effects in the same way (because it is +) as the ionization of benzoic acids but by much more \( (10^{1.6} \) times more) because it is 2.6 instead of 1.0. We already know what the mechanism of this reaction is:
The first step is quite like the ionization of benzoic acid. A negative charge is appearing on
the carbonyl oxygen atom and that negative charge will be stabilized by electron-withdrawing X groups. If the first step is rate determining, a positive $\rho$ makes sense.

We need now to look at some other reactions to get a grasp of the meaning of the value of
the Hammett $\rho$.

**The Hammett reaction constant $\rho$ measures the sensitivity of the reaction to electronic effects.**

- A positive $\rho$ value means more electrons in the transition state than in the starting material.
- A negative $\rho$ value means fewer electrons in the transition state than in the starting material.

![Typical Hammett plots](image)

**Equilibria with positive Hammett $\rho$ values**

To take a simple example, let’s just see what happens to $\rho$ if we simply move the carboxylic acid away from the ring. The $\rho$ value for ionization gets less. This is just what you would expect—the further it is from the aromatic ring, the less the acid cares about how electron rich or poor the ring is. With two saturated carbons between the benzene ring and the carboxylic acid, there is almost no effect on $pK_a$. But restore electronic communications with a double bond, and $\rho$ goes back up again.

![Equilibria](image)

If the negative charge on the anion can actually be delocalized round the ring, as it can in substituted phenols, we should expect the size of $\rho$ to increase. Both the phenol and the anion are delocalized but delocalization is more important for the anion. The effect is even more significant for the ionization of anilinium salts as the acid ArNH$_3^+$ does not have a delocalized lone pair but the conjugate base (ArNH$_2^-$) does.

![Reactions](image)

**Reactions with positive Hammett $\rho$ values**

The size and sign of the value of $\rho$ tell us about what is happening in the rate-determining step of a reaction. Any reaction that involves nucleophilic attack on a carbonyl group as the rate-
The determining step is going to have a ρ value of about 2–3, the same as for the hydrolysis of esters, as we have already seen. Large positive ρ values usually indicate extra electrons in the transition state delocalized into the ring itself. A classic example is nucleophilic aromatic substitution by the addition–elimination mechanism (Chapter 22). The ρ value is +4.9, but even this large value does not mean a complete anion on the benzene ring as the nitro group, present in all cases, takes most of the negative charge. The substituent X merely helps.

We get the full value when there are no nitro groups to take the brunt of the negative charge. This vinylic substitution has a ρ value of +9.0. It cannot be an SN2 reaction or it would have a small ρ value and it cannot be an SN1 reaction or it would have a negative ρ value (fewer electrons in the transition state). It must be an addition–elimination mechanism through a benzyllic anion delocalized round both benzene rings.

Reactions with negative Hammett ρ values

Negative ρ values mean electrons flowing away from the ring. A representative example is the SN2 displacement of iodide from EtI by phenoxide anions. This has a ρ value of exactly −1.0. Although the transition state has a negative charge, that charge is decreasing on the aromatic ring as the starting material approaches the transition state.

An SN1 reaction on the carbon atom next to the ring has a large negative ρ value. In this example, a tertiary benzylic cation is the intermediate and the rate-determining step is, of course, the formation of the cation. The cation is next to the ring but delocalized round it and the ρ value is −4.5, about the same value, though negative, as that for the nucleophilic substitution on nitrobenzenes by the addition–elimination mechanism that we saw in the last section.

The largest negative ρ values come from electrophilic aromatic substitution (Chapter 21), where the electrons of the ring are used in the reaction, leaving a positive charge on the ring itself in the intermediate. Some of this charge is already there in the transition state. This simple nitration has ρ = −6.4 and ρ values for electrophilic aromatic substitution are usually in the range −5 to −9. Negative ρ values mean electrons flowing out of the ring.
Reactions with small Hammett $\rho$ values

Small Hammett $\rho$ values arise in three ways. The aromatic ring being used as a probe for the mechanism may simply be too far away for the result to be significant. This trivial case of the alkaline hydrolysis of the 3-aryl propionate ester has a $\rho$ value of $+0.5$ and it is surprising that it is even that large.

The second case is the informative one where the reaction is not dependent on electrons flowing into or out of the ring. Pericyclic reactions are important examples and the Diels–Alder reaction of arylbutadienes with maleic anhydride shows a small negative $\rho$ value of $-0.6$. The small value is consistent with a mechanism not involving charge accumulation or dispersal, but the sign is interesting. We explained this type of Diels–Alder reaction in Chapter 34 by using the HOMO of the diene and the LUMO of the dienophile. The negative sign of $\rho$, small though it is, supports this view because the reaction is somewhat faster with electron-donating groups on Ar, which raise the energy of the HOMO of the diene.

The third case is in many ways the most interesting. We have seen that the alkaline hydrolysis of ethyl esters of benzoic acids (ArCO$_2$Et) has a $\rho$ value of $+2.6$ and that this is a reasonable value for a reaction involving nucleophilic attack on a carbonyl group conjugated with the aromatic ring. The hydrolysis of the same esters in acid solution, which also involves nucleophilic attack on the same carbonyl group, has a $\rho$ value of $+0.1$. In other words, substituted benzoic esters hydrolyse at more or less the same rate in acid solution, irrespective of their substituents. We need to look at the full mechanism to explain this remarkable result.

Steps 1, 3, and 5 cannot be slow as they are just proton transfers between oxygen atoms, and proton transfer between electronegative atoms is always fast. That leaves only steps 2 and 4 as possible rate-determining steps. The bimolecular addition of the weak nucleophile water to the low concentration of protonated ester (step 2) is the most attractive candidate, as step 4—the unimolecular loss of ethanol and re-formation of the carbonyl group—should be fast. What $\rho$ value would be expected for the reaction if step 2 were the rate-determining step? It would be made up of two parts. There would be an equilibrium $\rho$ value for the protonation step and a reaction $\rho$ value for the addition of water. Step 1 involves electrons flowing out of the molecule and step 2 involves electrons flowing in so the $\rho$ values for these two steps would...
have opposite charges. We know that the \( \rho \) value for step 2 would be about +2.5 (it’s just like the step in the ester hydrolysis) and a value of about −2.5 for the equilibrium protonation is reasonable. This is indeed the explanation: step 2 is the rate-determining step and the \( \rho \) values for steps 1 and 2 almost cancel each other out. All steps before the rate-determining step are present in the rate equation and also affect the Hammett \( \rho \) value.

**Summary: interpreting Hammett \( \rho \) values**

- large positive \( \rho \) values: positive charge on ring or delocalized round benzene ring
- moderate positive \( \rho \) values: electrons flow into transition state negative charge near ring loss of conjugation
- small \( \rho \) values: 1. Ar too far away 2. No electron change 3. Two \( \rho \)-values cancel each other out
- moderate negative \( \rho \) values: electrons flow out of transition state positive charge near ring loss of conjugation
- large negative \( \rho \) values: positive charge on ring or delocalized round benzene ring

You should not, of course, learn the numbers in this scheme, but you need an idea of roughly what each group of values means. You should see now why it is unimportant whether the Hammett correlation gives a good straight line or not. We just want to know whether \( \rho \) is + or − and whether it is, say, 3 or 6. It is meaningless to debate the significance of a \( \rho \) value of 3.4 as distinct from one of 3.8.

**Using the Hammett \( \rho \) values to uncover mechanisms**

Electrophilic attack on alkenes by bromine often goes through three-membered ring cyclic bromonium ions and we can sometimes tell that this is so by studying the stereochemistry. Here are two reactions of styrenes that look very similar—a reaction with bromine and another with PhSCl. With no further information, we might be tempted to assume that they both go by the same mechanism. However, the Hammett \( \rho \) values for the two reactions are rather different.

\[
\begin{align*}
X & \quad \text{Br} \\
\text{Br} & \quad \text{Cl} \\
\text{Br} & \quad \text{PhSCl} \\
\rho & = -2.7
\end{align*}
\]

The \( \rho \) value for bromination is definitely in the 'large' range and can only mean that a positive charge is formed that is delocalized round the benzene ring. Bromine evidently does not form a bromonium ion with these alkenes but prefers to form a secondary benzylic cation instead, which can be stabilized more effectively by delocalization.

\[
\begin{align*}
X & \quad \text{Br} \quad \text{Br} \\
\text{Br} & \quad \text{Cl} \\
\text{Br} & \quad \text{Br} \\
\rho & = -5.7
\end{align*}
\]

The sulfenylation, on the other hand, has a moderate negative \( \rho \) value. No cation is formed that is delocalized round the ring, but electrons flow out of the ring and we suspect some loss of conjugation. All this fits well with the formation of a three-membered ring intermediate. From experiments like this we learn that PhSCl is much more likely than bromine to react stereospecifically with alkenes through cyclic cation intermediates.
A complete picture of the transition state from Hammett plots

More information can be gained on the mechanism of the reaction if two separate experiments can be carried out with the mechanistic probe inserted at two different sites on the reagents. If we are studying a reaction between a nucleophile and an electrophile, it may be possible to make Hammett plots from the variation of substituents on both reagents. The acylation of amines with acid chlorides is an example.

\[
\begin{align*}
\text{Cl} & \quad \text{O} \\
\text{H}_2\text{N} & \quad \text{O} \\
\text{N} & \quad \text{H} \\
\text{NH}_3 & \quad ++ \\
\end{align*}
\]

If we vary the structure of the acid chloride we get a \( \rho \) value of +1.2, typical of nucleophilic attack on the carbonyl group. If we vary the amine we get a \( \rho \) value of –3.2, typical of a reaction in which electrons that were conjugated round the ring move away to form a new bond. Comparing the numbers tells us the rate depends on the nucleophilicity of the amine 100 times more than on the electrophilicity of the acid chloride.

\[
\begin{align*}
\text{Cl} & \quad \text{O} \\
\text{H}_2\text{N} & \quad \text{O} \\
\text{N} & \quad \text{H}_2 \\
\text{Cl} & \quad \text{X} \\
\text{Y} & \quad \rho = + 1.2 \\
\end{align*}
\]

Non-linear Hammett plots

The Hammett plot for hydrolysis of the acid chlorides of benzoic acids in aqueous acetone is very odd indeed. Hammett plots need not be perfectly linear to give useful information, but this one is clearly made up of two intersecting straight lines. This might look like disaster at first but, in fact, it tells us something rather important. The right-hand part of the curve, where the more electron-withdrawing substituents lie, has a slope of +2.5: just what we should expect for rate-determining attack of water on the carbonyl group. As we go to less electron-withdrawing substituents, the rate of the reaction suddenly starts to increase as we pass the para-chloro compound and the left-hand part of the curve has a slope of –4.4.

What can this mean? If the reaction becomes faster as we pass the discontinuity in the curve—and it gets faster whether we go from right to left or left to right—there must be a change in mechanism. If there is a choice between two mechanisms, the faster of the two will operate. Mechanism 1 is the rate-determining nucleophilic attack by water on the carbonyl group.

The new mechanism goes faster for more electron-donating substituents and has quite a large negative \( \rho \) value, suggesting the formation of a cation in the rate-determining step. This mechanism (mechanism 2) must surely be the \( S_N1 \)-like preliminary formation of an acylium ion by loss of chloride ion.
When the Hammett plot bends the other way, so that the rate of the reaction decreases as it passes the discontinuity, we have a single mechanism with a change in rate-determining step. A reaction goes by the fastest possible mechanism but its rate is limited by the slowest of the steps in that mechanism. An example is the intramolecular Friedel–Crafts alkylation of a diphenyl derivative where the alkylating agent is a diarylmethanol attached to one of the benzene rings in the ortho position.

The carbocation intermediate in the Friedel–Crafts reaction (Chapter 21) is rather stable, being tertiary and benzylic, and the formation of the cation, normally the rate-determining step, with inevitably a negative \( \rho \) value, goes faster and faster as the electron-donating power of the substituents increases until it is faster than the cyclization, which becomes the rate-determining step. The cyclization puts electrons back into the carbocation and has a positive \( \rho \) value. As the two steps have more or less the reverse electron flow to and from the same carbon atom, it is reasonable for the size of \( \rho \) to be about the same but of opposite sign.

A reaction occurs by the faster of two possible mechanisms but by the slower of two possible rate-determining steps.

We shall see more examples of Hammett \( \rho \) values used in conjunction with other evidence as the chapter develops but now it is time to look at what other evidence is available.
Other kinetic evidence for reaction mechanisms

The kinetic isotope effect

Up to now you have probably (and rightly) assumed that isotopes of an element are chemically identical. They differ only in the number of neutrons in their nuclei: chemistry generally depends on charge, orbitals, and electrons. It may come as a surprise to find that this is not quite true. Isotopes may differ chemically, because some chemical properties do depend on atomic mass. However, this difference is only significant for hydrogen—no other element has one isotope twice as massive as another! Kinetic isotope effects are the changes in rate observed when a (¹H) hydrogen atom is replaced by a (²H) deuterium atom in the same reaction. For any reaction, the kinetic isotope effect (KIE) is defined as

\[ \text{KIE} = \frac{k_\text{H}}{k_\text{D}} \]

where \( k_\text{H} \) is the rate with a ¹H atom in the molecule and \( k_\text{D} \) is the rate with a ²H (deuterium, D) atom in the molecule.

How do kinetic isotope effects come about? Even in its lowest energy state a covalent bond never stops vibrating. If it did it would violate a fundamental physical principle, Heisenberg’s uncertainty principle, which states that position and momentum cannot be known exactly at the same time: a non-vibrating pair of atoms have precisely zero momentum and precisely fixed locations. The minimum vibrational energy a bond can have is called the zero point energy, and the zero point energy depends on the mass of the atoms attached to the bond—heavier atoms have a lower zero point energy than lighter ones.

In order to break a covalent bond, a certain amount of energy is required to separate the nuclei from their starting position. This energy has to raise the vibrational state of the bond to the point where it breaks. For the sake of argument, imagine taking a C–H bond in its lowest energy state and breaking it—the diagram shows the amount of energy required, which we can call \( \Delta G^\ddagger \text{H} \). Now do the same for a C–D bond: because the zero point energy of a C–D bond is smaller than that for a C–H bond, the C–D bond needs that little bit more energy \( \Delta G^\ddagger \text{D} \) to break: in other words a C–D bond is marginally stronger than a C–H bond. This means reactions in which C–H bonds break go faster than reactions in which C–D bonds break, providing the bond to H (or D) is involved in the rate-determining step. The theoretical maximum value of...
the KIE is about 7 for reactions at room temperature in which a bond to H or D is being broken. For example, the rates of these two eliminations can be compared, and $k_H/k_D$ turns out to be 7.1 at 25 °C.

In this case the fact that the KIE is non-zero tells us that the C–H (or C–D) bond is being broken during the rate-determining step, and so the reaction must be an E2 elimination. In E1 eliminations, the rate-determining step does not involve a breaking C–H bond.

In Chapter 21 we told you that the rate-determining step in the nitration of benzene was the attack of the electrophile on the benzene ring. This is easily verified by replacing the hydrogen atoms round the benzene ring with deuteriums. The rate of the reaction stays the same, so the C–H (or C–D) bonds cannot be involved in the rate-determining step. If the second step, which does involve the breaking of a C–H bond, were the rate-determining step it would go more slowly if the H were replaced by D.

By contrast, for the iodination of phenol in basic solution there is a deuterium isotope effect of $k_H/k_D = 4.1$. Clearly, the loss of the proton from the intermediate must now be the rate-determining step—the phenolate ion reacts so rapidly that the first step is faster than the second.

The deuterium isotope effect can add to the information from Hammett plots in building up a picture of a transition state. Three separate Hammett $\rho$ values can be measured for the elimination reaction and this information is very valuable. In addition, a large KIE $k_H/k_D = 7.1$ is observed for the hydrogen atom under attack.

It is no surprise that the base ($\text{ArO}^-$) donates electrons and the leaving group ($\text{ArSO}_3^-$) accepts them, as the $\rho$ values indicate. The large deuterium isotope effect tells us that the reaction is E2, but additional information comes from the moderate positive $\rho(Y)$ value for the aromatic ring adjacent to the proton being lost. It might have been expected that this ring is merely a spectator, but in fact the reaction must involve a build-up of negative charge, which can be stabilized by an electron-donating substituent Y. This can be explained if we assume
that the removal of the proton is slightly more advanced at the transition state than loss of the leaving group.

**Entropy of activation**

The entropy of activation, \( \Delta S^\ddagger \), of a reaction tells us about the increase or decrease in order in a reaction as the starting material goes to the transition state. A positive \( \Delta S^\ddagger \) means an increase in entropy or a decrease in order, and a negative \( \Delta S^\ddagger \) means an increase in order. Normally, unimolecular reactions in which one molecule gives two products have a positive \( \Delta S^\ddagger \) and bimolecular reactions have a negative \( \Delta S^\ddagger \). Fragmentations (Chapter 36), such as this decarbonylation in which one molecule fragments to three, have positive values of \( \Delta S^\ddagger \), in this case \( \Delta S^\ddagger = +36.8 \text{ J mol}^{-1} \text{ K}^{-1} \).

At the other extreme are cycloadditions (Chapter 34) such as the Diels–Alder reaction we examined a few pages back. Not only do two reagents become one product but a very precise orientation is required in the transition state, usually meaning a large negative \( \Delta S^\ddagger \). Diels–Alder reactions usually have \( \Delta S^\ddagger \) of about \(-120\) to \(-160 \text{ J mol}^{-1} \text{ K}^{-1} \). The classic cyclopentadiene addition to maleic anhydride has \( \Delta S^\ddagger = -144 \text{ J mol}^{-1} \text{ K}^{-1} \).

These numbers give you the range of entropies of activation you may expect to find. Large negative numbers are common but only small positive numbers are found. The largest negative numbers apply to bimolecular reactions where neither reagent is in great excess. Smaller negative numbers may mean a bimolecular reaction with solvent or some other reagent in large excess. The acid-catalysed opening of styrene oxides in methanol is a good example.

The Hammett \( \rho \) value of \(-4.1 \) suggests a carbocation intermediate, as does the regioselectivity of the reaction (MeOH attacks the benzylic position) but the stereochemistry (the reaction occurs with inversion) and a modest negative entropy of activation (\( \Delta S^\ddagger = -48 \text{ J mol}^{-1} \text{ K}^{-1} \))
suggest rather an $S_N2$ reaction with a loose transition state having substantial positive charge at the benzylic carbon. Neither piece of evidence alone would be enough to define the mechanism.

**Acid and base catalysis**

As you have seen throughout this book, acids and bases provide the most widely used ways of speeding up reactions. If you want to make an ester—add some acid. If you want to hydrolyse an ester—add some base. We explained in Chapter 12 the ways in which acid and base catalysts help reactions along, and we introduced you to the terms **specific acid** and **specific base**, **general acid** and **general base**. We will now look in a little more detail at these types of catalysis and give some pointers as to how to establish which of them, if any, is operative in any given reaction.

As a preliminary, let’s look at an example of **specific acid catalysis**. This is the kind operating in the reaction just above—epoxides don’t react with methanol but, if we protonate the epoxide first, then the reaction works. Specific acid catalysis protonates electrophiles and makes them more electrophilic.

We could, on the other hand, have reasoned that although methanol is not a good enough nucleophile, deprotonating with a base will make it into the much more nucleophilic methoxide, and the reaction will also work. This sort of base catalysis—deprotonating nucleophiles to make them more nucleophilic—is **specific base catalysis**.

**Specific acid catalysis**

Specific acid catalysis (SAC) involves a rapid protonation of the compound followed by the slow step, which is accelerated in comparison with the uncatalysed reaction because of the greater reactivity of the protonated compound. You have just seen an example with an epoxide; ester hydrolysis (or formation) is another, as you saw in Chapter 12.

A more interesting reaction is the dienone–phenol rearrangement. Rearrangement in the absence of acid is very slow but once the ketone oxygen is protonated, it occurs very rapidly.
Again we have fast equilibrium protonation, followed by a rate-determining step involving a reaction of the protonated species: this is SAC.

This catalysis depends only on the protonating power of the solution. The compound must be protonated to react, so the catalyst must be a strong enough acid to do the job. It is not necessary that every molecule is protonated—just enough to set the reaction going because the catalytic acid is regenerated at the end. In a specific acid catalysed reaction, the rate of the reaction depends on the pH of the reaction mixture. SAC works only if the pH is similar to, or below, the p\(K_a\) of the conjugate acid of the substrate, and the log of the rate of the reaction is proportional to the pH of the solution.

There is one rather remarkable experimental indication of this mechanism. If the reaction is carried out in a deuterated solvent (D\(_2\)O instead of H\(_2\)O) the rate of the reaction increases. This is a solvent isotope effect rather than a kinetic isotope effect and needs some explanation. If you examine the three examples of SAC in the previous pages you will see that they share these characteristics: a fast proton exchange is followed by a rate-determining step that does not involve the making or breaking of any bonds to hydrogen.

\[
\text{rate} = k[XH^+] 
\]

The concentration of the intermediate [XH\(^+\)] is related to the pH and to the concentration of the substrate by the equilibrium constant, \(K\), of the protonation. This gives us:

\[
\text{rate} = kK[H^+][X] 
\]

In the acid-catalysed reaction, the bond to H (or D) is not broken in the rate-determining step, so \(k\) cannot change when hydrogen is replaced by deuterium. That means that if a reaction goes faster in D\(_2\)O than in H\(_2\)O then it must be \(K\) that is different (i.e. larger) in D\(_2\)O. SAC is more effective with D\(_2\)O\(^+\) in D\(_2\)O than with H\(_2\)O\(^+\) in H\(_2\)O because more of the substrate is protonated at any one time.

- An inverse solvent isotope effect (\(k[D_2O] > k[H_2O]\)) is indicative of specific acid catalysis.

This is sometimes explained by saying that D\(_2\)O\(^+\) is a stronger acid than H\(_2\)O\(^+\). This is partly true. The full truth is that D\(_2\)O\(^+\) in D\(_2\)O is a stronger acid than H\(_2\)O\(^+\) in H\(_2\)O. Water (H\(_2\)O) is a better solvating agent for H\(_2\)O\(^+\) than D\(_2\)O is for D\(_2\)O\(^+\) because O–H bonds are longer than O–D bonds. Look again at the potential energy curve we showed you on p. 1050 and reproduced below, this time representing the energies of O–H and O–D bonds. The average length of a bond is the mid-point of the line in the potential energy well representing its energy level. You can easily see that the mid-point for the O–H is further out than the mid-point for the O–D bond because of the asymmetry of the well. O–H bonds are longer than O–D bonds, and can therefore make stronger hydrogen bonds. These hydrogen bonds are better at allowing solvation of H\(_2\)O\(^+\), making H\(_2\)O\(^+\) in H\(_2\)O less willing to protonate a substrate than D\(_2\)O\(^+\) in D\(_2\)O.
Let’s illustrate all this with an example. The Z allylic alcohol below dehydrates in acid solution to the E diene. We have lots of data on this mechanism, all summarized in the diagrams. You may like to note as well that the product contains no deuterium after dehydation in D₂O.

\[
\rho = -6.0 \quad k(H_2O) = 1.0 \quad k(D_2O) = 2.5
\]

\[
\Delta S^\ddagger = +24 \text{ J mol}^{-1} \text{ K}^{-1}
\]

The Hammett \( \rho \) value of –6.0 suggests a carbocation intermediate and the positive entropy of activation suggests a rate-determining step in which disorder increases, perhaps one molecule breaking into two. The inverse solvent deuterium isotope effect (faster reaction in D₂O than in H₂O) strongly suggests SAC. Putting all this together we have a mechanism—a simple example of SAC. There is no protonation at carbon.

---

**Summary of features of specific acid catalysis**

1. Only H₃O⁺ is an effective catalyst; pH alone matters.
2. Usually means rate-determining reaction of protonated species.
3. Effective only at pHs near or below the pK₆ of the substrate's conjugate acid.
4. Proton transfer is not involved in the rate-determining step.
5. Only simple unimolecular and bimolecular steps—moderate + or –\( \Delta S^\ddagger \).
6. Inverse solvent isotope effect \( k(H_2O) < k(D_2O) \).

---

**Specific base catalysis**

The other side of the coin is specific base catalysis (SBC). SBC usually involves the removal of a proton from the substrate in a fast pre-equilibrium step followed by a rate-determining reaction of the anion. Most of the base-catalysed reactions you are familiar with work by SBC. Examples include opening of epoxides with thiols.
As with SAC, the rate of the reaction depends on the pH of the solution. If it is around or higher than the pK\textsubscript{a} of the thiol, thiolate anion will be formed and this opens the epoxide much faster than does the unionized thiol. The nucleophile is then regenerated by the oxyanion produced in the rate-determining step.

It is quite common for specific acid and specific base catalysis to operate on the same reaction, depending on the pH at which the reaction is carried out. In fact, you have already seen this for ester hydrolysis in Chapter 12. The pH–rate profile (Chapter 12) for the hydrolysis of a simple ester such as ethyl acetate shows just two straight lines meeting each other (and zero rate) at about neutrality. Ethyl acetate hydrolysis occurs by SAC or SBC only.

\[
\text{variation of rate of ester hydrolysis with pH}
\]

Removal of a proton from heteroatoms by heteroatom bases is never rate determining because it is always fast, but removal of a proton from carbon can be the rate-determining step. A remarkably large inverse solvent deuterium isotope effect was found with this elimination of a tertiary amine in basic solution.

\[
\frac{k(\text{H}_2\text{O})}{k(\text{D}_2\text{O})} = 1.0 \quad 7.7
\]

The detailed mechanism cannot be E2 or the isotope effect, if any, would be the other way round. With SBC, however, the mechanism can be E1cB having a carbanion as an intermediate.

\[
\text{The isotope effect observed is certainly inverse (the reaction is faster with H}_2\text{O than D}_2\text{O) but the magnitude of the effect is too large to be a solvent isotope effect and looks much more like an inverse kinetic isotope effect. And so it is. The tertiary amine is not a very good leaving group in spite of its positive charge (pK}_a\text{ of R}_3\text{NH}^+\text{ is about 10) so the carbanion mostly reverts to starting materials. The isotope effect is a kinetic isotope effect on this reverse step—the protonation of the carbanion. This reaction involves a proton transfer from H}_2\text{O or D}_2\text{O and will be much faster (7.7 times in fact) in H}_2\text{O due to an ordinary kinetic isotope effect. The elimination reaction goes faster in D}_2\text{O because the back reaction goes more slowly and more of the carbanion goes on to product.}
\]

**Microscopic reversibility**

There is only one least-energy pathway between two interconverting compounds such as the starting material and the intermediate here. Every microscopic detail of the back reaction is exactly the same as that for the forward reaction. This is the principle of microscopic reversibility. Here we use evidence from the back reaction (slow proton transfer from water to the carbanion) to tell us about the forward reaction.

**Summary of features of specific base catalysis**

1. Only HO\textsuperscript{−} is an effective catalyst; pH alone matters.
2. Usually means rate-determining reaction of deprotonated species.
3. Effective only at pHs near or above the pK\textsubscript{a} of the substrate.
4. Proton transfer is not involved in the rate-determining step, unless C–H bonds are involved.
5. Only simple unimolecular and bimolecular steps—moderate $+\Delta S^\ddagger$.
6. Inverse solvent isotope effect $k(\text{H}_2\text{O}) < k(\text{D}_2\text{O})$. 

$E1$, $E2$, and $E1cB$ mechanisms are described in Chapter 17.
General base catalysis

In Chapter 12 (p. 263) we pointed out that even weak bases—too weak to deprotonate a nucleophile by the mechanism we have just described for SBC—can still act as catalysts. Such catalysts are known as general base catalysts, and are the promoters of a parallel kind of acid–base catalysis called ‘general’ rather than ‘specific’. General base catalysis, abbreviated GBC, depends not only on pH (i.e. the concentration of hydroxide ion) but also on the concentration of other bases too. General acid catalysis, abbreviated GAC, likewise depends not only on pH (i.e. the concentration of H\textsubscript{3}O\textsuperscript{+}) but also on the concentration of other undissociated acids HA. General acid–base catalysis is a milder kind of catalysis and is characteristic of reactions catalysed by enzymes in the metabolism of living things.

In a general base-catalysed reaction, proton transfer is not complete before the rate-determining step (as it was in SBC) but occurs during the rate-determining step. A simple example is the catalysis by acetate ion of the formation of esters from alcohols and acetic anhydride.

\[
\text{nucleophile} + \text{electrophile} + \text{catalyst} \rightarrow \text{product} + \text{catalyst, regenerated}
\]

How can this catalysis work? At first sight there seems to be no mechanism available. Acetate cannot act as a specific base—it is far too weak (pK\textsubscript{a} AcOH 4.7) to remove a proton from an alcohol (pK\textsubscript{a} about 15). It can’t operate as a nucleophile, as pyridine does (p. 200), as nucleophilic attack on acetic anhydride would be a non-reaction, simply regenerating starting materials. The only thing it can do is to remove the proton from the alcohol as the reaction occurs.

\[
\text{nucleophile} \quad \text{electrophile} \quad \text{general base catalyst} \quad \text{rate-determining step} \quad \text{product} \\
\]

You will see at once that there is a great disadvantage in this mechanism: the rate-determining step is termolecular—three molecules have to collide. This comes out most clearly in the entropy of activation, which has an enormous negative value—around \(\Delta S^\ddagger = -168\ \text{J} \text{mol}^{-1} \text{K}^{-1}\) for this reaction. For this reason, GBC or GAC reactions are normally effective only if one of the three molecules is present in large excess—this reaction might be done in ROH as a solvent, for example, so that ROH is always present. We would also expect a normal kinetic isotope effect for ROD compared with ROH as a bond to hydrogen is being formed and broken in the rate-determining step: it is \(k_H/k_D = 2.4\) here.

In understanding how this GBC works it is helpful to look at the mechanism without catalysis.

\[
\text{nucleophile} \quad \text{electrophile} \quad \text{rate-determining step} \quad \text{product} \\
\]

The acetate catalyst cannot remove a proton from the starting material but it can easily remove a proton from the intermediate, which has a complete positive charge on the alcohol oxygen atom. The starting material has a pK\textsubscript{a} above the pK\textsubscript{a} of HOAc but the product has a pK\textsubscript{a} well below it. Somewhere in the middle of the rate-determining step, the pK\textsubscript{a} of the ROH proton passes through the pK\textsubscript{a} of acetic acid and then acetate is a strong enough base to remove it. The GBC is effectively deprotonating the transition state.

There was some discussion of this reaction in Chapter 12. Chapter 10 refers to the difficulty of pinpointing proton transfers in mechanisms involving the carbonyl group.

The first time you met third-order kinetics (where it arose from a combination of more than one step, see p. 261) we pointed out how unlikely real termolecular steps are.
So how do we find GAC or GBC? Well, first we must remove the more powerful ‘specific’ style of catalysis by working at constant pH because SAC or SBC depends on pH alone. If we find that the rate of the reaction changes with the concentration of a weak base at constant pH, we have GBC. The formation of three- and five-membered cyclic ethers shows the contrast between GBC and SBC. The formation of epoxides is straightforward SBC with a simple linear dependence on pH between pH 8 and 12, and no acceleration at constant pH by carbonate (CO$_3^{2-}$) ions. There is an inverse solvent isotope effect and an aryl substituent at the electrophilic carbon atom gives the small positive $\rho$ value expected for SN2 with an anion.

Formation of tetrahydrofuran (THF) is also faster at higher pH but, by contrast, is additionally accelerated by various bases at constant pH. If anions of phenols (ArO$^-$) are used as catalysts, a Hammett $\rho$ value of +0.8 shows that electrons are flowing away from the aromatic ring. There is a small normal kinetic isotope effect $k(H)/k(D) = 1.4$. Both SBC and GBC are therefore operating in this reaction. Here is the mechanism with ArO$^-$ as GBC.

Why are the two different? The THF is easy to form, the transition state is unstrained, and only a little help is needed to make the reaction go—GBC will do. The epoxide is very strained indeed and the starting material needs to be raised in energy before cyclization will occur. Only the most powerful form of catalysis—SBC—is good enough.

- **Summary of features of general base catalysis**
  1. Any base is an effective catalyst; pH also matters.
  2. Proton transfer is involved in the rate-determining step.
  3. Effective at neutral pHs even if below the pK$_a$ of the substrate.
  4. Catalyst often much too weak a base to deprotonate the reagent.
  5. Catalyst removes a proton, which is becoming more acidic in the rate-determining step.
  6. Some other bond making or bond breaking also involved unless proton is on carbon.
  7. Often termolecular rate-determining step: large $-\Delta S^\ddagger$.
  8. Normal kinetic isotope effect $k(H) > k(D)$.

**General acid catalysis**

GAC involves transfer of a proton from a weak acid (too weak to protonate the substrate completely) during the rate-determining step. A few examples will demonstrate to you how this works. They are all examples where GAC occurs because of a modification to a familiar reaction involving SAC.

In the first one, the termolecular problem (i.e. the fact that in GAC and GBC three molecules have to come together in the transition state) is avoided by making a reaction intramolecular. Normally, ester formation and hydrolysis are specific-acid-catalysed only, but here there is catalysis by a weak acid: acetic acid. A normal kinetic isotope effect $k$(HOAc)/$k$(DOAc) = 2.3 shows that proton transfer occurs in the rate-determining step and there is a large negative $\Delta S^\ddagger = -156$ J mol$^{-1}$ K$^{-1}$. This is GAC of nucleophilic attack on a carbonyl group, admittedly in a rather special molecule.
In Chapter 11 we emphasized the importance of the mechanism for the formation and hydrolysis of acetals. These are SAC reactions: alcohols are bad leaving groups and usually need to be fully protonated by strong acids before they will go, even with the help of the lone pair of another oxygen atom.

If we speed up the slow step by adding to the molecule some feature that stabilizes the cation intermediate, GAC may be found. One example is the aromatic cation formed in the hydrolysis of cycloheptatrienone acetals. The normal kinetic isotope effect announces the appearance of GAC.

Even adding one extra alkoxy group so that we have an orthoester instead of an acetal is enough. These compounds show catalysis with a variety of weak acids at not very acidic pH (5–6). As one OMe group is protonated, two others help in pushing it out, and they both help to stabilize the intermediate cation. Nature prefers these milder methods of catalysis, as we will see in Chapter 42.

For another contrast between SAC and GAC we need only refer you back to the two Z/E isomerizations earlier in the chapter. Isomerization of the diene is GAC—protonation at carbon is the slow step—and isomerization of the allylic alcohol is SAC. What we didn’t tell you earlier was that the GAC reaction has a normal kinetic isotope effect of $k(H)/k(D) = 2.5$ and a negative entropy of activation $\Delta S^\ddagger = -36$ J mol$^{-1}$ K$^{-1}$—just what we should expect for a bimolecular reaction involving rate-determining proton transfer from oxygen to carbon. Notice that the intermediate cation is the same whichever the route; only the ways of getting there, including the rate-determining steps, are different.
These examples show you that GAC is possible with strong acids, especially when protonation is at carbon and that in such cases no other bond-making or -breaking steps need be involved.

**Summary of features of general acid catalysis**

1. Any acid is an effective catalyst; pH also matters.
2. Proton transfer is involved in the rate-determining step.
3. Effective at neutral pHs even if above the pKₐ of the conjugate acid of the substrate.
4. Catalyst often much too weak an acid to protonate reagent.
5. Catalyst adds proton to a site that is becoming more basic in the rate-determining step.
6. Some other bond-making or bond-breaking also involved unless proton is on carbon.
7. Often termolecular rate-determining step: large −ΔS°.
8. Normal kinetic isotope effect k(H) > k(D).

The detection of intermediates

In earlier chapters we revealed how some reactive intermediates can be prepared, usually under special conditions rather different from those of the reaction under study, as a reassurance that some of these unlikely looking species can have real existence. Intermediates of this kind include the carbocation in the S₈₁ reaction (Chapter 15), the cations and anions in electrophilic (Chapter 21) and nucleophilic (Chapter 22) aromatic substitutions, and the enols and enolates in various reactions of carbonyl compounds (Chapters 20, 25, and 26). We have also used labelling in this chapter to show that symmetrical intermediates are probably involved in, for example, nucleophilic aromatic substitution with a benzyne intermediate (Chapter 22).

We have hedged this evidence around with caution since the fact that an intermediate can be prepared does not by any means prove that it is involved in a reaction mechanism. In this section we are going to consider other and better evidence for intermediates and at the same time revise some of the earlier material.

Trapping reactions

A more impressive piece of evidence is the design of a molecule that has built into it a functional group that could react with the intermediate in a predictable way but could not reasonably react with other species that might be present. For example, aromatic ethers react with nitrating agents in the ortho or para positions (Chapter 21). The intermediate has a positive charge delocalized over three of the carbon atoms in the benzene ring. If a nucleophilic group is built into the structure in the right way, it might trap this intermediate and stop it reacting further.

If we try drawing a mechanism for the formation of this remarkable compound, we discover that a necessary intermediate is also an intermediate in our preferred mechanism for aromatic nitration. The amide has trapped the cation we would propose as an intermediate in aromatic nitration.
nitration, so we feel more confident about that mechanism. The product is an enol ether that will hydrolyse to the observed enone.

This mechanism explains everything, including the stereochemistry. The NO₂⁻ attacks the aromatic ring para to the OMe group and on the opposite side to the amide. The amide is now in the perfect position to capture the cation at the meta position and, because the tether is short, it must form a cis bridge.

To be convincing, evidence for an intermediate should include:

- detection of the intermediate in the reaction mixture, perhaps by a trapping reaction
- a demonstration that the intermediate gives the product when added to the reaction mixture (this also means that it must be prepared as an at least reasonably stable compound)
- kinetic evidence that the rate of formation and rate of disappearance are adequate
- other suitable evidence of the kind that we have been discussing in this chapter.

A neat intramolecular trap for a benzyne works in this way. A standard benzyne-generating reaction, the diazotization of an ortho-amino benzoic acid (Chapter 22), gives a zwitterion that loses nitrogen and CO₂ to release the benzyne. A furan tethered to the next ortho position traps the benzyne in an intramolecular Diels–Alder reaction. The yield is impressive and the trap is very efficient.

This reaction cannot really be explained without a benzyne intermediate. This same method of making benzyne is used on other o-amino benzoic acids and so we deduce that they presumably create benzenes too.

**A collection of reactions linked by a common intermediate**

Particularly convincing evidence can develop when a number of chemists suggest the same intermediate for a number of different reactions and show that it is possible to trap the intermediate from one reaction, put it into the others, and get the normal products. We are going to describe one such set of related reactions. In Chapter 36 we suggested a mechanism for the Favorskii rearrangement involving a series of remarkable intermediates. Here is an example.
We’ll summarize the evidence on this particular example. If the reaction is run in MeOD instead of MeOH, the starting material becomes deuterated at the site of enolate formation, suggesting that this is a fast and reversible step. The entropy of activation for the reaction is $\Delta S^\ddagger = +64 \text{ J mol}^{-1} \text{ K}^{-1}$, suggesting that the slow step is one molecule breaking into two. There is only one such step—the second, ionization step. If various substituted phenyl groups are used, the Hammett $\rho$ value is $-5$. This large negative value also suggests that the ionization is the slow step as the cation is delocalized into the benzene ring.

There is evidence for the first intermediate—the exchange of deuterium from the solvent. In fact formation of the enolate can even become the rate-determining step. If we merely add an extra methyl group to the chloroketone the reaction becomes 220 times faster and the rate-determining step changes. There is no longer any exchange of deuterium from the solvent and the Hammett $\rho$ value changes from $-5$ to $+1.4$. This small positive value, showing some modest increase in electron density near the ring, matches typical known $\rho$ values for enolate formation.

However, it’s not too surprising that an enolate ion is formed from a ketone in basic solution. The oxyallyl cation is a much more unusual species. How can we be convinced that it really is an intermediate? One way is to make it by an alternative route. If basic nucleophiles such as the methoxide ion are avoided and reaction of zinc with an $\alpha,\alpha'$-dibromoketone in a non-nucleophilic solvent like diglyme is used instead, the oxyallyl cation can be trapped in a Diels–Alder reaction. This is the basis for a good synthesis of seven-membered rings.

But does the oxyallyl cation go on to give cyclopropanones? In fact, there is good evidence that the two are in equilibrium. If the same method is used to create the diphenyl oxyallyl cation in methanol instead of in diglyme, the normal Favorskii product is produced. Evidently, methoxide is needed only to produce the enolate—methanol alone is enough to decompose the cyclopropanone.

Further information comes from another reaction. If a suitable (1,3-di-t-butyl) allene is epoxidized with $m$-CPBA the unstable allene oxide can actually be isolated. On heating, this
epoxide gives a stable trans-di-t-butylcyclopropanone. It is very difficult to see how this reaction could happen except via the oxyallyl cation intermediate.

![Reaction Diagram]

But can the same cyclopropanone be an intermediate in the Favorskii reaction? If the bromoketone is treated with methoxide in methanol, it gives the Favorskii product, but if it is treated with a much more hindered base, such as the potassium phenoxide shown, it gives the same cyclopropanone.

![Reaction Diagram]

Other, less stable, cyclopropanones—such as this 2,2-dimethyl compound—can be made by carbene addition (Chapter 38) to ketenes. This compound did the Favorskii reaction with methoxide in methanol: the only product came from the expected loss of the less unstable carbanion. This will, of course, be general acid catalysed by methanol as no free carbanion can be released into an alcoholic solvent.

![Reaction Diagram]

The same cyclopropanone gives a cycloadduct with furans—this must surely be a reaction of the oxyallyl cation and we can conclude that the isomeric reactive intermediates are in equilibrium, and react to give products according to the conditions they find themselves in.

![Reaction Diagram]

Although it is never possible to prove a mechanism, this interlocking network of intermediates, all known to be formed under the reaction conditions, all being trapped in various ways, and all known to give the products, is very convincing. If any part of the mechanism were not correct, that would throw doubt on all the other reactions as well.

**Stereochemistry and mechanism**

Although we have left stereochemistry to the last, it is one of the most important tools in unravelling complex mechanisms. You have already seen how inversion of configuration is a vital piece of evidence for an $S_N2$ mechanism (Chapter 15) while retention of configuration is the best evidence for participation (Chapter 36). You have seen the array of stereochemical evidence for pericyclic mechanisms (Chapters 34 and 35). The chapters devoted to diastereoselectivity (32 and 33) give many examples where information about the mechanism follows from the stereochemistry. We shall not go over that material again, but summarize the types of evidence with new examples. The first example looks too trivial to mention.
Retention or inversion?

Although this reaction looks like a simple $S_N2$ displacement by the naphthyl oxide anion on the primary alkyl chloride, there is, in fact, a reasonable alternative—the opening of the epoxide at the less hindered primary centre followed by closure of the epoxide the other way round. The electrophile is known as epichlorohydrin and has two reasonable sites for nucleophilic attack.

It looks difficult to tell these mechanisms apart since both involve the same kind of reaction. Stereochemistry is the answer. If enantiomerically pure epichlorohydrin is used, the two mechanisms give different enantiomers of the product. Although each $S_N2$ reaction takes place at a primary centre and the stereogenic centre remains the same, the products shown in orange and in brown are obviously enantiomers.

Finding out the mechanism of this process is not idle curiosity as a group of drugs used to combat high blood pressure and heart disease, such as propranolol, are made from epichlorohydrin and it is essential to know which enantiomer to use to get the right enantiomer of the drug. In fact, the epoxide is attacked initially, in preference to the chloride.

A more complicated example arises from the strange reactions used to make malic acid from chloral and ketene. An initial $[2 + 2]$ cycloaddition is followed by acid treatment and then treatment with an excess of aqueous NaOH. Neutralization gives malic acid.

The mechanism of this reaction also looks straightforward: normal ester hydrolysis followed by hydrolysis of the CCl$_3$ group to CO$_2$H. Caution suggests investigation, particularly as four-membered lactones sometimes hydrolyse by $S_N2$ displacement at the saturated ester carbon rather than by attack on the carbonyl group, like the three-membered lactones discussed in Chapter 36 (p. 934). The solution was urgently needed when it was found that enantiomerically pure lactone could be prepared as a single enantiomer. The sequence was repeated with enantiomerically pure lactone: lactone hydrolysis occurred with retention of configuration and must be normal ester hydrolysis by attack of water at the carbonyl group. But the hydrolysis of the CCl$_3$ group surprisingly occurred with inversion of configuration.
The answer must be a mechanism related to the one we have just seen for epichlorohydrin. Attack by hydroxide on CCl₃ is almost unknown and it is much more likely that intramolecular attack by alkoxide to give an epoxide should occur. The carboxylate anion can then invert the stereogenic centre by intramolecular S_N2 displacement. Notice that the tether ensures attack at the nearer end of the epoxide. The second four-membered lactone also hydrolyses by attack at the carbonyl group.

**The Ritter reaction and the Beckmann fragmentation**

Another collection of related intermediates occurs in the Ritter reaction and the Beckmann fragmentation. The Ritter reaction involves the combination of a tertiary alcohol and a nitrile in acid solution and the proposed mechanism involves a series of intermediates.

**Ritter reaction**

Evidence that the two reactions are intimately related comes from the formation of the same amide from two different starting materials: a tertiary alcohol and an oxime, both based on the decalin skeleton. The oxime has its OH group *anti* to the ring junction to minimize steric hindrance as oxime formation is under thermodynamic control (Chapter 11).

**Beckmann fragmentation**

The experiments also provide stereochemical evidence that a carbocation is an intermediate in both reactions. Both starting materials are *cis*-decalins but the product is a *trans*-decalin. The carbocation intermediate has no stereochemistry and can react with the nitrile from either face: since axial attack is preferred the product is the more stable *trans*-decalin. Here’s the mechanism for the Beckmann fragmentation:
It is also possible to trap the carbocation in other ways. The Beckmann fragmentation of this oxime of an aryl seven-membered ring ketone gives a tertiary carbocation that might be expected to cyclize to give an amide. However, this reaction would give an unfavourable eight-membered ring (see Chapter 32) and does not happen. Instead, the chain twists round the other way and forms a much more stable six-membered ring by intramolecular Friedel–Crafts alkylation.

In the Ritter reaction a rather different kind of evidence for the cation is the fact that families of isomeric alcohols all give the same product. In all these cases, rearrangements of the first-formed carbocation can easily account for the products. An example in the decalin series is this Ritter reaction with KCN as the nitrile in acidic solution so that HCN is the reagent. The starting material is a spirocyclic tertiary alcohol but the product is a trans-decalin formed by rearrangement.

Trapping the nitrilium cation is also possible. A famous example is the heterocycle (an oxazine, Chapter 32) produced by intramolecular capture of the nitrilium ion with a hydroxyl group. Note that the tertiary alcohol reacts to give the cation while the secondary alcohol acts as the nucleophilic trap.

An important example in which the diastereoisomer produced was critical in determining the mechanism is the synthesis of cis-aminindanol, a part of Merck’s anti-HIV drug Crixivan (indinavir). The reaction involves treatment of indene epoxide with acetonitrile (MeCN) in acidic solution. The product is a cis fused heterocycle. It is easy to see which atoms have come from the nitrile (green) but the substitution of nitrogen for oxygen at one end of the epoxide has occurred with retention of configuration as the cis-epoxide has given the cis product. Clearly, we have some sort of Ritter reaction and the nitrilium ion has been trapped with an OH group.
What about the regioselectivity? The obvious explanation is that a cation is formed from the epoxide by a specific acid-catalysed ring opening. But why should the nitrile attack the bottom face of the cation? We should expect it to attack the top face preferentially as the hydroxyl group partly blocks the bottom face.

A reasonable suggestion is that the nitrile adds reversibly to the cation. Every time it adds to the top face, it drops off again as the OH group cannot reach round to form the heterocycle. But every time it adds to the bottom face (which may well be less often), it is quickly captured by the OH group because 5,5 fused rings are favourable when the ring junction is cis. Eventually, all the compound is converted to the heterocycle.

The mechanism of this reaction is of great importance because it is the foundation stone of the synthesis of Crixivan (indinavir)—an anti-HIV drug that has saved thousands of lives.

**Summary of methods for the investigation of mechanism**

This brief summary is for guidance only and the figures quoted are approximate ranges only. The full text above should be used for detail. All methods would not be used in one investigation.

1. **Make sure of the structure of the product**
   - Basic structure (Chapters 3, 13, and 18) and stereochemistry (Chapter 31) by spectroscopic methods.
   - Detail of the fate of individual atoms by labelling with D, 13C, and 18O. Double labelling may help.
   - The stereochemical course of the reaction (enantio- or diastereoselectivity) may be critical.

2. **Kinetic methods**
   - Rate equation gives the composition of main transition state.
   - Deuterium isotope effect: \( k_H > k_D \) shows bond to H formed and/or broken in transition state. Values of \( k_H/k_D \) of 2–7 typical.
   - Entropy of activation shows increase (\( \Delta S^\ddagger \) positive) or decrease (\( \Delta S^\ddagger \) negative) in disorder. Typical values and deductions:
     - \( \Delta S^\ddagger \) positive (rarely larger than \(+50 \text{ J mol}^{-1} \text{ K}^{-1}\)): one molecule breaks into two or three
     - moderate negative values: no change in number of molecules (one goes to one etc.) or bimolecular reaction with solvent
large negative values: two molecules go to one or unimolecular reaction with ordered transition state (cycloaddition, etc.)

3. Correlation of structure and reactivity
   - Replace one group by another of similar size but different electronic demand (CF₃ for CH₃ or OMe for CH₃).
   - Systematic Hammett σ/ρ correlation with m- and p-substituted benzenes:
     - sign of ρ: +ρ indicates electrons flowing into and –ρ electrons flowing out of ring in transition state
     - magnitude of ρ shows effect on the benzene ring:
       - large (around 5), charge on ring (+p, anion; –p, cation)
       - moderate (around 2–4), charge on atom next to ring—may be gain or loss of conjugation
       - small (<1), ring may be distant from scene of action or ρ may be balance of two ρs of opposite sign.

4. Catalysis
   - pH–rate profile reveals specific acid or base catalysis.
   - Rate variation with [HA] or [B] at constant pH reveals GAC or GBC.
   - Deuterium isotope effect: normal (k_H > k_D) shows GA/BC, inverse solvent k(D₂O) > k(H₂O) shows SA/BC.
   - GA/BC is termolecular and has large negative entropy of activation.

5. Intermediates
   - Independent preparation or, better, isolation from or detection in reaction mixture helps.
   - Must show that intermediate gives product under reaction conditions.
   - Designed trapping experiments often most convincing.

Transition metals extend the range of organic reactions

Some of the most exciting reactions in organic chemistry make use of transition metals, and in recent years three Nobel prizes have been awarded for work in this area. How about this example? It is a Heck reaction, which allows nucleophilic addition to an unactivated alkene. Just a catalytic amount of palladium is needed to make the reaction go: the most useful organometallic reactions are those in which the metal acts catalytically.

\[

\end{align*}
\]

Reagents and complexes containing transition metals are important in modern organic synthesis because they allow apparently impossible reactions to occur easily. Their chemistry complements traditional functional group chemistry and significantly broadens the range of
reactions a chemist can expect to use to make molecules. This chapter introduces the concepts of metal–ligand interaction, describes the most important reactions that can occur while ligands are bound to the metal, and demonstrates the power of organometallic chemistry in synthesis. The efficiency of transition metal-catalysed reactions means that they are routinely used in industrial synthesis. It is important that you understand the rules by which organometallic chemistry works.

The 18 electron rule

There is a contradiction in what is required of a metal complex for it to be useful to us. Initially, it will need to be stable and have a long enough lifetime to enable study and, ideally, storage. But once it enters the reaction vessel, stability is a disadvantage: instead we want reactivity. Our ideal catalyst is a complex that is stable in the resting state, but quickly becomes activated in solution—perhaps by loss of a ligand—so that it can interact with the substrate. Fortunately, there is a simple guide to the stability of transition metal complexes: the 18 electron rule. If a complex satisfies the 18-electron rule it means that the metal at the centre of the complex has the noble gas configuration of 18 electrons in the valence shell, and the complex is likely to be stable. The requirement for 18 electrons comes from the need to fill one ‘s’ orbital, five ‘d’ orbitals, and three ‘p’ orbitals with two electrons in each. The 18 electrons we need can come from those the metal already possesses plus those donated by any coordinating ligands.

The table below gives you the number of valence electrons each metal starts with before it acquires any ligands. Notice that the ‘new’ group numbers 1–18 give you the answer without any calculation. The most important are highlighted.

Metals to the left-hand side of this list obviously need many more electrons to make up the magic 18. Chromium, for example, forms stable complexes with a benzene ring, giving it six electrons, and three molecules of carbon monoxide, giving it two each: 6 + 6 + 2 + 2 + 2 = 18. Palladium is happy with just four triphenylphosphines (Ph₃P) giving it two each: 10 + 2 + 2 + 2 + 2 = 18.

You may already know from your study of inorganic chemistry that there are exceptions to the 18-electron rule, particularly among complexes of Ti, Zr, Ni, Pd, and Pt, which can all form stable 16-electron complexes. The important 16-electron Pd(II) complex with two chlorides and two acetonitriles (MeCN) will feature heavily in this chapter. The so-called platinum metals Ni, Pd, and Pt are extremely important in catalytic processes, as you will see later on. Their stable 16-electron configuration results from a high-energy vacant orbital caused by the complex adopting a square planar geometry.

Ligands can be attached in many different ways

Transition metals can have a number of ligands attached to them and each ligand can be attached in more than one place. This affects the reactivity of the ligand and the metal because each additional point of attachment means the donation of more electrons. We can show the number of atoms involved in bonding to the metal by a hapto number η. A simple Grignard reagent is η¹ (pronounced ‘eta-one’) as the magnesium is attached only to one carbon atom. A metal–alkene complex is η² because both carbon atoms of the alkene are equally involved in bonding to the metal. In these cases the η designation is not very informative as there are no alternatives, and it is usually omitted.
The bonding in these two complexes is very different. In the first there is a simple \( \sigma \) bond between the metal and the alkyl group as in a Grignard reagent \( \text{R–MgBr} \) and this type of complex is called a \( \sigma \) complex. In the alkene complex, bonding is to the \( p \) orbitals only. There are no \( \sigma \) bonds to the metal, which sits in the middle of the \( \pi \) bond in between the two \( p \) orbitals. This type of complex is called a \( \pi \) complex.

Representing bonds in transition metal complexes

It is difficult to know exactly how to draw the bonding in metal complexes and there are often several different acceptable representations. There is no problem when the metal forms a \( \sigma \) bond to atoms such as \( \text{Cl or C} \) as the simple line we normally use for covalent bonds means exactly what it says. The problems arise with ligands that form \( \sigma \) bonds by donating both their electrons, and with \( \pi \) complexes. Everyone writes phosphine–borane complexes with two charges but we normally draw the same sort of bond between a phosphine and, say, \( \text{Pd} \) as a simple line with no charges.

\[
\text{Ph}_3\text{P} - \text{BH}_3 \quad \text{Ph}_3\text{P} - \text{BH}_3
\]

16 electrons 18 electrons

You will sometimes see \( \pi \) complexes drawn with simpler dotted lines going to the middle of the \( \pi \) bond, sometimes with dotted \( \pi \) bonds, and sometimes with bonds (simple or dotted) going to the ends of the old \( \pi \) bond. These are all acceptable as the bonding is complex, as you will see. We might almost say that the ambiguity is helpful: we often don’t know either the exact nature of the bonding or the number of other ligands in the complex. In the diagrams in this section we have shown the main bond from metal to ligand as a heavy line in the simplest representation but we also offer alternatives with simple and dotted bonds. Don’t worry about this—things will become clearer as the chapter develops. When you have to draw the structure of a complex but you don’t know the exact bonding, just draw a line from metal to ligand.

These labels are useful where there is a choice of type of bonding, as with allylic ligands. The metal can either form a \( \sigma \) bond to a single carbon (hence \( \eta^1 \)), or form a \( \pi \) complex with the \( p \) orbitals of all three carbons of the allyl system—this would be \( \eta^3 \). If the \( \pi \) complex is made from an allyl cation, the ligand has two electrons, but it has four if it is made from an allyl anion. Similarly, a cyclopentadienyl anion can act as a \( \sigma \) ligand (\( \eta^1 \)), an allyl ligand (\( \eta^3 \)), or, most usually, as a cyclopentadienyl ligand (\( \eta^5 \)). The distinction is very important for electron counting as these three different situations contribute two, four, or six electrons, respectively, to the complex.

Neutral ligands can also bond in a variety of ways. Cyclooctatetraene can act as an alkene (\( \eta^2 \)), a diene (\( \eta^4 \)), a triene (\( \eta^6 \)), or a tetaene (\( \eta^8 \)), and the reactivity of the ligand changes accordingly. These are all \( \pi \) complexes with the metal above or below the black portion of the ring and with the thick bond to the metal at right angles to the alkene plane.

To determine the number of electrons around the transition metal in a complex the valence electrons from the metal ion are added to those contributed by all the ligands. The numbers of electrons donated by various classes of ligands are summarized in the table. Anions such as halides, cyanide, alkoxide, hydride, and alkyl donate two electrons, as do neutral ligands with a lone pair such as phosphines, amines, ethers, sulfides, carbon monoxide, nitriles, and...
isonitriles. Unsaturated ligands can contribute as many as eight electrons and can be neutral or negatively charged. If the overall total is 18, then the complex is likely to be stable. If the overall total is less than 18 the complex is called coordinatively unsaturated.

Bonding and reactions in transition metal complexes

The majority of ligands have a lone pair of electrons in a filled $sp^n$ type orbital that can overlap with a vacant metal ‘$dsp$’ orbital, derived from the vacant d, p, and s orbitals of the metal, to form a conventional two-electron two-centre $\sigma$ bond. Ligands of this type increase the electron density on the central metal atom.

A bonding interaction is also possible between any filled d orbitals on the metal and vacant ligand orbitals of appropriate symmetry such as $\pi^*$ orbitals. This leads to a reduction of electron density on the metal and is known as back-bonding. An example would be a complex with carbon monoxide. Many metals form these complexes and they are known as metal carbonyls. The ligand (CO) donates the lone pair on carbon into an empty orbital on the metal while the metal donates electrons into the low-energy $\pi^*$ orbital of CO. Direct evidence for this back-bonding is an increase in the C–O bond length and a lowering of the infrared stretching frequency from the population of the $\pi^*$ orbital of the carbonyl.

When an unsaturated ligand such as an alkene approaches the metal sideways to form a $\pi$ complex, similar interactions lead to bonding. The filled $\pi$ orbitals of the ligand bond to empty d orbitals of the metal, while filled d orbitals on the metal bond to the empty $\pi^*$ orbitals of the ligand. The result is a $\pi$ complex with the metal–alkene bond perpendicular to the plane of the alkene. The bond has both $\sigma$ and $\pi$ character.

Coordination to a metal by any of these bonding methods changes the reactivity of the ligands dramatically and this is exploited in the organometallic chemistry we will be discussing in the rest of the chapter. You do not need to understand all the bonding properties of metal complexes but you need to be able to count electrons, to recognize both $\sigma$ and $\pi$ complexes, and to realize that complexes show a balance between electron donation and electron withdrawal by the metal.

Oxidative addition inserts metal atoms into single bonds

Potential ligands that do not have a lone pair or filled $\pi$-type orbital are still able to interact with transition metal complexes but only by breaking a $\sigma$ bond. This is the first step in a wide variety of processes and is described as oxidative addition because the formal oxidation state of the transition metal is raised by two, for example M(0) to M(II), in the process. This is the result of having two extra ligands bearing a formal negative charge. You have seen this process in the formation of Grignard reagents (Chapter 9).
The number of coordinated ligands also increases by two so the starting complex is usually in low oxidation state (0 or 1; the diagram shows 0) and coordinatively unsaturated, that is, it has an empty site for a ligand and, say, only 16 electrons, like (MeCN)2PdCl2, whereas the product is usually coordinatively saturated, that is, it cannot accept another ligand unless it loses one first.

Oxidative addition occurs for a number of useful neutral species, including molecular hydrogen, carbon–hydrogen bonds, and silanes as well as polarized bonds or electrophilic species containing at least one electronegative atom. The resulting species with metal–ligand bonds allow useful chemical transformations to occur. Important examples include the oxidative addition of Pd(0) to aryl iodides and the activation of Wilkinson’s catalyst for hydrogenation in solution by oxidative addition to a hydrogen molecule.

Vaska’s complex

There are a number of possible mechanisms for oxidative addition and the precise one followed depends on the nature of the reacting partners. Vaska’s complex [Ir(PPh3)2COCl] has been extensively studied and it reacts differently with hydrogen and methyl iodide. Hydrogen is added in a cis fashion, consistent with concerted formation of the two new iridium–hydrogen bonds. The 16e (count them!), d8, Ir(I) complex becomes a new 18e, d6, Ir(III) species. With methyl iodide the kinetic product is that of trans addition, which is geometrically impossible from a concerted process. Instead, an SN2-like mechanism is followed involving nucleophilic displacement of iodide followed by ionic recombination.

Reductive elimination removes metal atoms and forms new single bonds

If we want to use organometallic chemistry to make organic compounds other than those containing metals, we must be able to remove the ligands from the coordination sphere of the metal at the end of the reaction. Neutral organic species such as alkenes, phosphines, and carbon monoxide can simply dissociate in the presence of other suitable ligands but those that are bound to the metal with shared electrons require a more active process. Fortunately, most reactions that occur around a transition metal are reversible and so the reverse of oxidative addition, known as reductive elimination, provides a simple route for the release of neutral organic products from a complex. Our general reaction shows M(II) going to M(0), releasing X–Y. These two ligands were separate in the complex but are bound together in the product. A new X–Y σ bond has been formed.
The ligands to be eliminated must be cis to one another for reductive elimination to occur. This is because the process is concerted. Two examples from palladium chemistry make this point clear. Warming in DMSO causes ethane production from the first palladium complex because the two methyl groups are cis in the square planar complex. The more elaborate second bisphosphine forces the two methyl groups to be trans and reductive elimination does not occur under the same conditions.

Of course, no one wants to make ethane that way (if at all) but many other pairs of ligands can be coupled by reductive elimination. Reductive elimination is one of the most important methods for the removal of a transition metal from a reaction sequence, leaving a neutral organic product. We will see many examples as the chapter develops but here is an indole synthesis that depends on a reductive elimination at palladium as a last step. In the starting material, palladium has two σ bonds sharing electrons with C, and is Pd(II). In the reaction the two C substituents bond together to form the indole ring and a Pd(0) species is eliminated.

**Migratory insertion builds ligand structure**

Two ligands can also react together to produce a new complex that still has the composite ligand attached to the metal, ready for further modification. This process involves migration of one of the ligands from the metal to the other ligand, and insertion of one of the ligands into the other metal–ligand bond. It is known as **migratory insertion**. The insertion process is reversible and, as the metal effectively loses a ligand in the process, the overall insertion may be driven by the addition of extra external ligands (L) to produce a coordinatively saturated complex. As with reductive elimination, a cis arrangement of the ligands is required and the migrating group (X) retains its stereochemistry (if it has any) during the migration.

Wilkinson’s catalyst is used in homogeneous hydrogenation of alkenes. The catalyst is soluble in many organic solvents such as EtOH, chloroform, or some hydrocarbons. The alkene complexes with the metal and migratory insertion forms an alkyl metal complex by hydrogen transfer. The next step, reductive elimination, usually follows rapidly to give the alkane and a complex that adds a hydrogen molecule to regenerate the catalyst.
Migratory insertion is the principal way of building up the chain of an organic ligand before elimination. The group to be inserted must be unsaturated in order to accommodate the additional bonds and common examples include carbon monoxide, alkenes, and alkynes, producing metal–acyl, metal–alkyl, and metal–alkenyl complexes, respectively. In each case the insertion is driven by additional external ligands, which may be an increased pressure of carbon monoxide in the case of carbonylation or simply excess phosphine for alken and alkyne insertions. In principle, the chain extension process can be repeated indefinitely to produce polymers by Ziegler–Natta polymerization.

An example of the carbonylation process is the reaction of the tetracarbonyl ferrate dianion \([\text{Fe(CO)}_4]^{2-}\) with alkyl halides. This reagent is made by dissolving metal reduction of the 18-electron Fe(0) compound Fe(CO)₅. Addition of two electrons would give an unstable 20-electron species but the loss of one of the ligands with its two electrons restores the stable 18-electron structure.

This iron anion is a good soft nucleophile for alkyl halides and can be used twice over to produce first a monoanion with one alkyl group and then a neutral complex with two alkyl groups and four CO ligands. Each of these complexes has 18 electrons. If extra CO is added by increasing the pressure, CO inserts into one Fe–C bond to form an iron acyl complex. Finally, reductive elimination couples the acyl group to the other alkyl group in a conceptually simple ketone synthesis. It does not matter which Fe–C bond accepts the CO molecule: the same unsymmetrical ketone is produced at the end.

Any good two-electron ligand will cause the CO insertion: \(\text{Ph}_3\text{P}\) is often used instead of an increased CO pressure. The phosphine adds to the iron and pushes out the poorest ligand (one of the alkyl groups) on to a CO ligand in a process of ligand migration. We can represent this as the mechanism below, although the phosphine addition and alkyl migration may well be concerted to avoid the formation of a 20-electron complex as an intermediate.
Carbon monoxide incorporation extends the carbon chain

Carbonylation (the addition of carbon monoxide to organic molecules) is an important industrial process as carbon monoxide is a convenient one-carbon feedstock and the resulting metal–acyl complexes can be converted into aldehydes, acids, and their derivatives. The OXO process is the hydroformylation of alkenes such as propene and uses two migratory insertions to make higher value aldehydes. Although a mixture is formed, this is acceptable from very cheap and abundant starting materials. Here the metal complex is a catalyst, not a stoichiometric reagent.

A catalytic cycle (going clockwise from the top) shows the various stages of alkene coordination, hydrometallation (migratory insertion) to produce an alkyl metal species, coordination of carbon monoxide followed by another migratory insertion, and finally reductive cleavage with hydrogen to produce the metal–hydride intermediate, which is then ready for another cycle. The steps leading to the other regioisomeric aldehyde and the ligands on the metal are omitted for clarity.

The mechanisms of the two key migratory insertion steps are worth discussion. Hydrometallation occurs by initial \( \pi \) complex formation followed by addition of the metal to one end of the alkene and hydrogen to the other. Both of the possible regioisomers are formed. The carbonyl insertion reaction is another migration from the metal to the carbon atom of a CO ligand.

Insertion reactions are reversible

The reverse process, decarbonylation, is also fast but can be arrested by maintaining a pressure of carbon monoxide above the reaction mixture. The reverse of hydrometallation involves the elimination of a hydride from the adjacent carbon of a metal alkyl to form an alkene complex.
This process is known as β hydride elimination or simply β elimination. It requires a vacant site on the metal as the number of ligands increases in the process and so is favoured by the shortage of ligands in 16-electron complexes. In more complex structures, the metal and the hydride must be syn to each other on the carbon chain for the elimination to be possible. The product is an alkene complex that can lose the neutral alkene simply by ligand exchange. β elimination is an important final step in a number of transition-metal catalysed processes, but it can be a nuisance because Pd–Et (and other similar Pd–alkyl) complexes cannot be used as β elimination is too fast.

Palladium is the most widely used metal in homogeneous catalysis

These elementary steps form the basis for most of organo-transition metal chemistry, and are the same regardless of the metal and the detailed structure of the ligands. Transition metal catalysis is an enormous and rapidly expanding field that we just do not have the space to discuss in comprehensive detail. Instead, we will concentrate on the chemistry of one important, and representative, transition metal: palladium. Pd-catalysed reactions are widely used in both industrial and academic laboratories, on both a minute and very large scale. The variety of reactions that can be catalysed by Pd together with the range of functional groups tolerated, and usually excellent chemo- and regioselectivity, means that most syntheses of organic molecules of any complexity will now involve palladium chemistry in one or more key steps.

Choice of palladium complex

There are many available complexes of palladium(0) and palladium(II). Tetrakis(triphenylphosphine)palladium(0), Pd(PPh₃)₄, and tris(dibenzylidene-acetone)dipalladium(0), Pd₂(dba)₃, or the chloroform complex, Pd₂(dba)₃·CHCl₃, which is air-stable, are the most common sources of palladium(0). The detailed structures of some palladium complexes, particularly the dimers, are beyond the scope of this book but we will discuss the reactions in detail. Palladium(II) complexes are generally more stable than their palladium(0) counterparts. The dichloride PdCl₂ exists as a polymer and is relatively insoluble in most organic solvents. However, (PhCN)₂PdCl₂ and (MeCN)₂PdCl₂ (both easily prepared from PdCl₂) are soluble forms of PdCl₂, as the nitrile ligands are readily displaced in solution. Bis(phosphine)palladium(II) chloride complexes are also air-stable and readily prepared from PdCl₂. Palladium is, of course, an expensive metal—these complexes cost about £50–100 per gram—but very little is needed for a catalytic reaction.

Let’s start with a review of the basic chemistry of palladium, as you will be seeing many more examples of these steps in specialized situations. Palladium chemistry is dominated by two oxidation states. The lower, palladium(0), present in tetrakis(triphenylphosphine)palladium, for example, is nominally electron-rich, and will undergo oxidative addition with suitable substrates such as organic halides, resulting in a palladium(II) complex. Oxidative addition is thought to occur on the coordinatively unsaturated 14-electron complex, formed by ligand dissociation in solution.
The resulting Pd–R \( \sigma \) bond in such complexes is very reactive, especially towards carbon–carbon \( \pi \) bonds. Thus an alkene in the reacting system will lead to coordination followed by migratory insertion into the palladium–carbon \( \sigma \) bond. Like hydrometallation this process is a migratory insertion and is called **carbopalladation** because carbon and palladium become attached to the ends of the alkene system. There is no change in oxidation state during this process, although the ligands (often phosphines) must dissociate to allow coordination of the alkene and associate to provide a stable final 16-electron product.

With some metals the process of olefin coordination and insertion may continue, leading to polymerization, but with palladium the metal is expelled from the molecule by a \( \beta \)-hydride elimination reaction and the product is an alkene, plus a Pd(II) complex. For the whole process to be catalytic, this Pd(II) product of \( \beta \)-hydride elimination must be converted to a Pd(0). This occurs in the presence of base, which removes HX from the palladium(II) species. This is another example of reductive elimination: one that forms a hydrogen halide rather than a carbon–carbon or carbon–hydrogen bond, as you saw earlier.

The speed of the \( \beta \)-hydride elimination (which is intramolecular and very fast) means that the original substrate for the oxidative addition reaction must be chosen with care—the presence of hydrogen at an sp\(^3\) carbon in the \( \beta \) position must be avoided. Thus, substrates for oxidative addition reactions in palladium chemistry are frequently vinylic, allylic, or aromatic and never ethyl or \( n \)-propyl.

**The Heck reaction couples together an organic halide or triflate and an alkene**

All the individual steps outlined above combine to make up the catalytic pathway in the **Heck reaction** with which we started the chapter. The Heck reaction couples an alkene with an organic halide or triflate \( \text{R}^1 \text{--X} \) to form a new alkene. The \( \text{R}^1 \) group in \( \text{R}^1 \text{--X} \) can be aryl, vinyl, or any alkyl group without \( \beta \) hydrogens on an sp\(^3\) carbon atom. The group X can be a halogen (Br or I) or triflate (\( \text{OSO}_2\text{CF}_3 \)). The alkene can be mono- or disubstituted and can be electron-rich, -poor, or -neutral. The base need not be at all strong and can be \( \text{Et}_3\text{N} \), NaOAc, or aqueous Na\(_2\)CO\(_3\). The reaction is very accommodating!

**Triflates**

The triflate (trifluoromethanesulfonate) anion, \( \text{CF}_3\text{SO}_2^- \), or TfO\(^-\), is an excellent, non-basic leaving group. It is often used as an oxygen-based alternative to halides, and metals will insert into the C--OSO\(_2\text{CF}_3\) bond. Triflates, particularly aryl and vinyl triflates, can be made conveniently with Comins’ reagent.
This palladium-catalysed addition of aryl, vinyl, or substituted vinyl groups to organic halides or triflates is one of the most synthetically useful palladium-catalysed reactions. The method is very efficient, and carries out a transformation that is difficult by more traditional techniques. The mechanism involves the oxidative addition of the halide, insertion of the olefin, and elimination of the product by a β-hydride elimination process. A base then regenerates the palladium(0) catalyst. The whole process is a catalytic cycle.

Here is the Heck reaction at work coupling two heterocyclic substrates. Easy chemistry to do, but impossible without a Pd catalyst.

Notice the regioselectivity: unlike the carbonylation on p. 1077, the Heck reaction favours one isomer, and when the alkene is polarized by an electron-withdrawing group the new C–C bond forms at the other end of the alkene. Notice also in this example and those below that the Pd is added as Pd(II), not Pd(0): the box below explains how this works.

The mild conditions of the Heck reaction mean that protected amino acids can be made without any racemization. The two examples below use a more hindered analogue of triphenyl phosphine, but the mechanism is the same.

**In situ formation of Pd(0) by reduction of Pd(II)**

In reactions requiring palladium(0), formation of the active complex may be achieved more conveniently by reduction of a palladium(II) complex, for example Pd(OAc)₂. Any phosphine may then be used in the reaction, without the need to synthesize and isolate the corresponding palladium(0)–phosphine complex. The reduction of palladium(II) to palladium(0) can be achieved with amines, phosphines, alkenes, and organometallics such as DIBAL-H, butyllithium, or trialkylaluminium. The mechanisms are worth surveying as they illustrate the basic steps of organometallic chemistry.
In contrast, electron-donating groups such as ethers lead to attack at the end of the alkene substituted by oxygen to produce the 1,1-disubstituted product. These reactions must be dominated by the interaction of the filled π orbital of the alkene with an empty d orbital on Pd. In the example below, the Heck reaction works even in the absence of a phosphine ligand.

Because β-hydride elimination is reversible, when there is a choice the more stable of the possible alkenes usually results. The reaction of allylic alcohols is particularly important as the more stable of the two alkenes is the enol and a carbonyl compound is formed.

**Hydropalladation–dehydropalladation can lead to alkene isomerization**

Reversible β-hydride eliminations provide a mechanism for interconverting regioisomers of an alkene, and the following reaction sequence also illustrates another point about the reductive elimination step: it is a syn elimination, and the C–Pd and C–H bonds have to eclipse one another for the Pd–H bond to form. Oxidative addition of the aryl iodide to a palladium(0) complex, formed from Pd(OAc)$_2$ by reduction, gives the active palladium(II) complex ArPdOAcL$_2$. Carbopalladation occurs as expected on an electron-rich alkene to give the product of aryl addition to the oxygen end of the alkene in a syn fashion. β-Hydride elimination must occur away from the aryl group because there is only one C–H bond syn to the C–Pd bond. The alkene has moved one position round the ring.
Hydropalladation in the reverse sense gives a new $\sigma$ complex, which could eliminate either the black or the green hydrogens. Elimination of the green H gives the enol ether, which is the most stable alkene possible due to conjugation.

This product now undergoes a second Heck reaction involving naphthyl iodide:

The initial mechanism is much the same. However, the enol ether has two diastereotopic faces: syn or anti to the aromatic substituent (Ar$^1$) introduced in the first step. Palladium is very sensitive to steric effects and generally forms less hindered complexes where possible, so the palladium(II) complexes the face of the enol ether anti to Ar$^1$. This in turn controls all the subsequent steps, which must be syn, leading to a final product with anti stereocchemistry. The requirement for syn $\beta$-hydride elimination also explains the regiochemical preference of the elimination. In the $\sigma$-bonded cyclic structure there is only one hydrogen (green) that is syn to the palladium; the one on the carbon bearing the naphthyl substituent is anti and cannot be eliminated. Further migrations of the alkene by hydropalladation are prevented by the silver carbonate, which rapidly removes iodide from the intermediate, preventing readdition of Pd–H to the alkene.

Cross-coupling of organometallics and halides

Other than $\beta$-hydride elimination, another important pathway by which palladium(II) intermediates can lead to neutral organic fragments is reductive elimination. This forms the basis of the mechanism for cross-coupling reactions between an organometallic reagent and an organic halide or triflate.

This is a reaction that seems very attractive for synthesis but, in the absence of a transition metal catalyst, the yields are very low. We showed in Chapter 27 how vinyl silanes can be made with control over stereochemistry and converted into lithium derivatives with retention. Neither of these vinyl metals couple with vinyl halides alone. But in the presence of a transition metal—Cu(I) for Li and Pd(0) for Sn—coupling occurs stereospecifically and in good yield.
The mechanism of palladium-catalysed cross-coupling starts, as in the Heck reaction, with oxidative addition of the halide or triflate to the initial palladium(0) phosphine complex to form a palladium(II) species. But the next step is new: it is a transmetalation, so-called because the nucleophile (R₁) is transferred from the metal in the organometallic reagent to the palladium and the counternion (X = halide or triflate) moves in the opposite direction. The new palladium(II) complex with two organic ligands undergoes reductive elimination to give the coupled product and the palladium(0) catalyst, ready for another cycle.

The reaction is important because it allows the coupling of two different components (R₁ and R₂), distinguished by being bonded either to the metal M or to the halide or triflate X. Both components form σ complexes with Pd but the halide partner (R₂X) bonds first by oxidative addition and this R₂–Pd bond must survive while the metal partner (R₁M) transfers R₁ to Pd by transmetalation. Once the two components are joined to the palladium atom, only the cross-coupled product can be formed. R₂X combines with Pd(0) and R₁M with Pd(II). There can then be no confusion. In contrast to the Heck reaction, here the metal defines the location of the new C–Pd bond.

The halide partner (R₂X) must be chosen with care, as β-hydride elimination would decompose the first intermediate during the slow transmetalation step. The choice for R₂ is restricted to substituents without β-hydrogen atoms on sp³ carbon atoms: vinyl, allyl, benzyl, and polyfluoroalkyl halides, triflates, and phosphates have all been coupled successfully. The organometallic reagent (R₁M) can be based on magnesium, zinc, copper, tin, silicon, zirconium, aluminium, or boron and the organic fragment can have a wide variety of structures as coupling is faster than β-hydride elimination.

Named coupling reactions
Palladium-catalysed reactions involving organometallic partners based on B, Mg, Sn, and Zn are particularly important and are often referred to by the names of their discoverers: Suzuki coupling for B, Kumada coupling for Mg, Stille coupling for Sn, and Negishi coupling for Zn.
In spite of the wide range of organometallic reagents that can be used there are two classes that have proved particularly popular because they are stable intermediates in their own right and can be prepared and purified separately before the coupling reaction. These cross-couplings are known by the names of the two chemists whose work made the reactions so valuable. The Stille coupling employs a stannane as the organometallic component (R\textsubscript{1}M) while the Suzuki coupling relies on a boronic acid.

### The Stille coupling uses stannanes as the organometallic component

Since its discovery in the late 1970s, the Stille coupling has been widely used for the coupling of both aromatic and vinylic systems.

The mechanism involves the oxidative addition of the vinyl or aromatic triflate or halide to give an organopalladium intermediate. Transmetallation with the organostannane forms another organopalladium intermediate with two Pd–C σ bonds. A reductive elimination step releases the product and thereby regenerates the palladium(0) catalyst. Vinyl triflates can be made from enolizable aldehydes or ketones and aryl triflates from phenols, but the reaction also works with vinyl and aryl halides.

The Stille reaction is widely used to make bonds between sp\textsuperscript{2} carbon atoms, but it also works with sp carbons: the example below is a challenging formation of a 10-membered ring containing two alkynes.

The Stille coupling may be combined with carbonylation in two ways. Acid chlorides may be used as substrates for the reaction with vinyl or aryl stannanes, although an atmosphere of carbon monoxide is frequently required to prevent decarbonylation after the oxidative addition step.
Simply performing a normal Stille reaction in the presence of carbon monoxide may also lead to carbonylated products. These reactions can take place in a CO saturated solution, under one atmosphere of pressure. Using these conditions, excellent yields of the carbonylated product can be obtained, without any of the normal coupling product being present.

\[
\text{PhI} + \text{Me}_3\text{SnOEt} \xrightarrow{\text{catalytic Pd(PPh}_3)_4/\text{CO}, 1,4\text{-dioxane}} \text{OEt} \equiv \text{CO} + \text{OEt} \\
\text{not formed}
\]

The mechanism follows that of a normal Stille coupling except that the carbon monoxide first exchanges for one of the phosphine ligands and then very rapidly inserts to produce an acyl palladium(II) complex. Transmetalation with the vinyl stannane in the usual way forms trimethylstannyl iodide and the key palladium complex carrying two carbon ligands. Transmetalation is always the slow step in these coupling reactions, allowing time for the carbon monoxide insertion. The final step—reductive elimination—releases the Pd(0) catalyst for the next cycle.

**Interactive mechanism for the carbonylative Stille coupling catalytic cycle**

**Acyl palladium species react like activated acid derivatives**

Carbonylation of a halide or triflate provides a direct route to a range of chain-extended acyl derivatives. A carbonyl group substituted with PdX (X = halide or triflate) is a reactive acylating agent, rather like an acid anhydride, as PdX is a good leaving group. Reaction with alcohols and amines gives esters and amides, while reduction with tributyltin hydride gives the aldehyde. Intramolecular attack by alcohols leads to lactones, as demonstrated in the conversion of a vinyl iodide into a 2H-furanone (butenolide). We will see more of these reactions later.

**The Suzuki coupling couples boronic acids to halides**

The Suzuki coupling of a boronic acid or ester with a vinyl or aryl halide or triflate is probably the most commonly used of all cross-coupling reactions. The original version, first reported in 1979, involved hydroboration of an alkyne with catecholborane, followed by palladium(0)-catalysed coupling of the resulting vinyl boronate with an aromatic iodide or bromide. The hydroboration is generally regioselective for the less hindered position and addition of boron and hydrogen occurs cis stereospecifically.
As in the Stille coupling, the geometry of both unsaturated components is preserved during the coupling so this is an excellent method for the stereoselective synthesis of dienes. Hydroboration of octyne followed by hydrolysis of the boronate gave exclusively the E-vinyl boronic acid. Coupling with the Z-vinyl bromide in toluene with palladium(0) catalysis with potassium hydroxide as the base gave the E,Z-diene in good yield. These dienes are very useful in the Diels–Alder reaction (Chapter 34).

\[ \text{H-BO}_2 \text{C}_6\text{H}_{13} \xrightarrow{1. \text{heat}} \text{C}_6\text{H}_{13} \text{C}_6\text{H}_{13} \xrightarrow{2. \text{H}_2\text{O}} \text{B(OH)}_2 \text{C}_6\text{H}_{13} \]

90% yield 75% yield

This sort of reaction has been used in the synthesis of the unsaturated units of a range of natural products, including trisporol B. The key step is the stereocontrolled synthesis of an \(E,Z\)-diene. The geometry of both double bonds comes stereospecifically with retention of configuration from single geometrical isomers of the starting materials.

The mechanism of the Suzuki coupling is very similar to that of the Stille coupling. Oxidative addition of the vinylic or aromatic halide to the palladium(0) complex generates a palladium(II) intermediate. This then undergoes a transmetallation with the alkenyl boronate, from which the product is expelled by reductive elimination, regenerating the palladium(0) catalyst. The important difference is the transmetallation step, which explains the need for an additional base, usually sodium or potassium ethoxide or hydroxide, in the Suzuki coupling. The base accelerates the transmetallation step, leading to the borate directly, presumably via a more nucleophilic ‘ate’ complex.

Sterically demanding substrates are tolerated well and Suzuki coupling is often used for aryl–aryl cross-couplings. This example has three ortho substituents around the newly formed bond (marked in black) and still goes in excellent yield.

Aromatic heterocycles also couple well. The 2-position of a pyridine is very electrophilic and not at all nucleophilic (Chapter 29) but couplings at this position are fine with either the
halide or the boronic acid in that position. Clearly, it is a mistake to see either of these substituents as contributing a ‘nucleophilic carbon’. It is better to see the reaction as a coupling of two equal partners with the two substituents (the halide and the boronic acid) as control elements to ensure cross-coupling and prevent dimerization.

**Coupling to alkynes: the Sonogashira reaction**

The coupling of terminal alkynes with aryl or vinyl halides under palladium catalysis is known as the Sonogashira reaction and is rather like the Heck reaction. It is a catalytic process, requiring a palladium(0) complex; it is performed in the presence of base, and generally uses copper iodide as a co-catalyst. One partner—the aryl or vinyl halide—is the same as in the Stille and Suzuki couplings but the alkyne needs no metal to activate it: the reaction works with the alkyne itself.

The mild conditions usually employed, frequently room temperature, mean that the reaction can be used with thermally sensitive substrates. By now, you should not be surprised by the mechanism! Oxidative addition of the organic halide gives a palladium(II) intermediate that undergoes transmetallation with the alkynyl copper (generated from the terminal alkyne, base, and copper iodide). Reductive elimination with coupling of the two organic ligands gives the product and regenerates the palladium(0) catalyst.

It is usually more convenient, as in the Heck reaction, to use a stable and soluble Pd(II) derivative such as bis(triphenylphosphine)palladium(II) chloride instead of Pd(0). This is rapidly reduced in situ to give a coordinatively unsaturated, catalytically active, palladium(0) species. The geometry of the alkene is generally preserved so that cis (Z) and trans (E) dichloroethylene give the two different geometrical isomers of the enyne below in >99% stereochemical purity as well as excellent yield.
Ene-diynes and the Bergmann cyclization

The Sonogashira reaction provides an important way to make the ene-diyne antibiotics. Symmetrical ene-diynes may be synthesized in one step from two molecules of a terminal alkyne and Z-dihaloethylene. The ene-diyne part of the molecule does the remarkable Bergmann cyclization to give a benzene diradical; the ene-diyne is able to penetrate DNA and the diradical is able to react with it, giving the compounds anticancer activity. To make the most biologically active compounds, however, the reaction is performed sequentially, allowing different functionality on each of the alkyne units.

Allylic electrophiles are activated by palladium(0)

Allylic compounds with good leaving groups, such as bromide and iodide, are excellent allylating agents but they suffer from loss of regiochemistry due to competition between the direct \(S_n2\) and \(S_n2'\) reactions. This problem was described in Chapter 24. In contrast, \(\pi\)-allyl...
cation complexes of palladium allow both the stereochemistry and regiochemistry of nucleophilic displacement reactions to be controlled.

In addition, leaving groups (X) that are usually regarded as rather unreactive still work, which makes the purification and handling of the starting materials easier. Acetate (X=OAc) is the most commonly used leaving group, but a range of other functional groups (X=OCO₂R, OPO(OR)₂, Cl, Br, OPh) will perform a similar role. The full catalytic cycle is shown below, with the intermediate π-allyl complex in equilibrium between the neutral version, which has the leaving group coordinated to palladium, and the cationic π-allyl complex.

Soft nucleophiles generally give the best results: stabilized enolates such as malonates, or cyanide, are best for carbon–carbon bond formation, but for C–X (X=O, N, S) bond formation the reaction is successful with alkoxides, amines, and thiolates (RS⁻). In the example below an amine nucleophile attacks the allyl system to generate the more stable product with the double bond within the ring.

The intramolecular reaction works well to give heterocyclic rings—the regioselectivity is usually determined by the length of the chain and how far it can reach. Here a 6/5 fused product is preferred to a bridged product containing two seven-membered rings.

The reaction usually proceeds with retention of configuration at the reacting centre. As in S₈₂ substitution reactions going with retention (Chapter 36), this actually suggests a double inversion. Coordination of Pd to the double bond of the allylic acetate occurs on the less hindered face opposite the leaving group and we can think of the oxidative addition step as an invertive nucleophilic displacement of the leaving group by a pair of Pd electrons. The nucleophile then adds to the face of the π-allyl Pd cation complex opposite the Pd. The net result is displacement of the leaving group by the nucleophile with retention. Thereafter, the
nucleophile attacks from the less hindered face of the resulting \( \pi \)-allyl complex (that is, away from the metal), leading to overall retention of configuration.

The reaction of this allylic acetate with the sodium salt of Meldrum's acid demonstrates the retention of configuration in the palladium(0)-catalysed process. The tetraacetate and the intermediate \( \pi \)-allyl complex are symmetrical, thus removing any ambiguity in the formation or reaction of the \( \pi \)-allyl complex and hence in the regiochemistry of the overall reaction.

Vinyl epoxides provide their own alkoxide base

Vinyl epoxides and allylic carbonates are especially useful electrophiles because under the influence of palladium(0) they generate an alkoxide base, so no added base is required with these substrates. The overall reaction proceeds under almost neutral conditions—ideal with complex and sensitive substrates. The relief of strain in the three-membered ring drives the reaction with palladium(0) to produce the zwitterionic intermediate. Proton transfer activates the nucleophile, and attack at the less hindered end of the \( \pi \)-allyl palladium intermediate preferentially leads to overall 1,4-addition of NuH.

Retention of stereochemistry is demonstrated by the reaction of a substituted malonate with epoxycyclopentadiene. Palladium adds to the side opposite the epoxide so the nucleophile is forced to add from the same side as the OH group. This, no doubt, helps 1,4-regioselectivity.

Allylic carbonates produce the required alkoxide by decarboxylation of the carbonate anion that is displaced in the formation of the \( \pi \)-allyl palladium intermediate. Deprotonation activates the nucleophile, which rapidly traps the \( \pi \)-allyl palladium complex to give the allylated product, regenerating the palladium(0) catalyst.
Trost and his group have used both of these palladium-catalysed alkylations in a synthesis of aristeromycin from epoxycyclopentadiene. The cis stereochemistry of this carbocyclic nucleotide analogue is of paramount importance and was completely controlled by retention of configuration in both substitutions.

The first reaction is between epoxycyclopentadiene and adenine, one of the heterocyclic building blocks of nucleic acids, and follows the mechanism we have just described to give a cis-1,4-disubstituted cyclopentene.

![Mechanism of palladium-catalysed alkylation](image)

The alcohol is then activated by conversion into the carbonate, which reacts with phenylsulfonylnitromethane, and could later be converted into an alcohol. Once again, retention of stereochemistry during the palladium-catalysed substitution gives the cis product.

![Steps of the alkylation reaction](image)

**Intramolecular alkylations make rings**

π-Allyl intermediates may also be used in cyclization reactions, including the synthesis of small and medium-sized rings using an intramolecular nucleophilic displacement. Three-membered rings form surprisingly easily, taking advantage of the fact that the leaving group can be remote from the nucleophile. The precursors can also be prepared by allylic alkylation. The sodium salts of malonate esters react with this monoacetate under palladium catalysis at the less hindered end to give the allylic alcohol.

![Steps of intramolecular alkylation](image)

Acetylation activates the second alcohol to displacement so that the combination of sodium hydride as base and palladium(0) catalyst leads to cyclization to the cyclopropane.

**Palladium can catalyse cycloaddition reactions**

The presence of five-membered rings such as cyclopentanes, cyclopentenes, and dihydrofurans in a wide range of target molecules has led to a variety of methods for their preparation. One of the most successful of these is the use of trimethylenemethane \([3 + 2]\) cycloaddition, catalysed by palladium(0) complexes. The trimethylenemethane unit in these reactions is derived from 2-\([(\text{trimethylsilyl})\text{methyl}]\)-2-propen-1-yl acetate, which is at the same time an allyl silane and an allylic acetate. This makes it both a weak nucleophile and an electrophile in the presence of palladium(0). Formation of the palladium π-allyl complex is followed by removal of the trimethylsilyl group by nucleophilic attack of the
resulting acetate ion, thus producing a zwitterionic palladium complex that can undergo cycloaddition reactions.

Trimethylenemethane
The symmetrical molecule with three CH₂ groups arranged trigonally about a carbon atom is interesting theoretically. It could have a singlet structure with two charges, both of which can be delocalized, but no neutral form can be drawn. Alternatively, it could be a triplet with the two unpaired electrons equally delocalized over the three CH₂ groups. This form is probably preferred and the singlet form is definitely known only as the palladium complex we are now describing. You might compare the singlet and triplet structures of trimethylenemethane with those of carbenes in Chapter 38.

The normal way to do the cycloadditions is to react the complex with an alkene bearing electron-withdrawing substituents that make the substrate prone to Michael-type conjugate addition. Cyclopentenones illustrate the reaction nicely.

The mechanism is thought to be stepwise (in other words, not a real cycloaddition at all) with conjugate addition of the carbanion followed by attack of the resulting enolate on the π-allyl palladium unit to form a new five-membered ring having an exo methylene group.

Palladium-catalysed amination of aromatic rings
You've seen that palladium catalysis helps form carbon–carbon bonds that are difficult to make using conventional reactions. It can also help form carbon–heteroatom bonds that are difficult to make, and you have already seen some examples in the reactions of π-allyl complexes. Work starting in the 1990s by Buchwald and Hartwig has shown that Pd can be used to promote nucleophilic substitution at a vinylic or aromatic centre—a reaction which would not normally be possible. For example, aromatic amines can be prepared directly from the corresponding bromides, iodides, or triflates and the required amine in the presence of palladium(0) and a strong alkoxide base.
The mechanisms and catalysts used in this ‘Buchwald–Hartwig’ chemistry mirror those of coupling reactions involving oxidative addition, transmetallation, and reductive elimination. The first step, as usual, is oxidative insertion of Pd(0) into the aryl–halogen bond. The Pd(II) complex now adds the amine so that both coupling partners find themselves bonded to the same palladium atom. The base eliminates H–I from the complex and reductive elimination forms the Ar–N bond.

Various bases, such as t-BuONa, MeONa, LiN(TMS)_2, or K_2CO_3, have been successful and some of the most successful ligands (coordinating groups shown in brown) are shown below. The fourth structure is a preformed complex used in catalytic amounts.

The range of compounds which can be made is very great: both electron-withdrawing and electron-donating substituents are acceptable; hindered compounds or those with acidic hydrogens such as phenols are tolerated. Even aryl chlorides, which are much cheaper than bromides or iodides, can also be successful.

Aromatic heterocyclic halides also work well whether they are electron-deficient or electron-rich. These couplings use the more hindered ligand shown in the margin.

It is tempting to view the amine as the ‘nucleophile’ in these reactions but it is clear that nucleophilicity has little to do with it as amides also couple to aromatic rings under similar conditions. The ability to act as a ligand for palladium is the important thing. The ligand xantphos (see above) is used in these reactions and again the nature of the substituents on the benzene ring is of little account. Even strained azetidines react well.
These reactions have been very widely used in the pharmaceutical industry in the making of medicinal compounds. When Sepracor wanted to make their anti-fungal compound itraconazole, it was obvious that they should make the two ends with stereochemistry and join them together with a central achiral section. Right in the middle is a piperazine ring joined to two different benzene rings, one connected through O and one through N. The C–N coupling chemistry of Buchwald and Hartwig could have been made for this problem.

We have already seen that p-bromophenol can be joined to an amine with palladium catalysis, so it should be easy to join it to piperazine. However, there is a potential problem of selectivity: we want to add this benzene ring just once, and the way to do this is to protect one nitrogen atom by reductive amination with benzaldehyde. The remaining NH group can then be coupled to the aromatic ring and the benzyl group removed by hydrogenation.

The workers at Sepracor then added the left-hand end of the molecule (we shall call this R1) to the free OH group. The other aromatic ring, already functionalized with the right-hand end of the molecule (we shall call this R2) was coupled as its bromide to the free NH group by a second Buchwald–Hartwig amination reaction process. It’s easy to see how this chemistry simplifies the assembly of such a large and complex molecule.

The bisphosphine BINAP is shown on p. 319. It is a chiral compound, but that is irrelevant to its use here.
Nucleophilic aromatic substitution and palladium catalysis compared

You will have noticed that Buchwald–Hartwig chemistry accomplishes the same as nucleophilic aromatic substitution (SNAr, Chapter 22): the replacement of a halogen by a nucleophile. So what are the differences?

The synthesis of a drug to control blood clotting gives us the opportunity to review both methods. This compound also has a central piperazine ring and disconnection of the right-hand side chain reveals an amine that could be functionalized by alkylation with a suitable benzylic halide or reductive amination.

A standard way to make aromatic amines is by nitration and reduction (Chapter 21) so we can think of making this aminobenzene from the nitrobenzene below. Now we can disconnect the two C–N bonds with the idea of putting a halide (X) at the point of substitution in each aromatic coupling partner.

The substituents on the right-hand ring are both electron withdrawing and are ortho and para to the leaving group. As you know from Chapter 22, this is perfect for ordinary nucleophilic aromatic substitution—so much so that chloride is a good enough choice and it is not necessary to use fluoride. The left-hand ring has again a good electron-withdrawing substituent but it is meta to the halide and so nucleophilic aromatic substitution will not work. Palladium catalysis is needed. Chemists at Berlex Biosciences chose to introduce the left-hand ring first.
Alkenes coordinated to palladium(II) are attacked by nucleophiles

Now for another case where a transition metal catalysis facilitates a reaction that would not occur under normal conditions: nucleophilic attack on an isolated double bond. Usually alkenes react with nucleophiles only when conjugated with an electron-withdrawing group. But coordination of an electron-rich alkene to a transition metal ion such as palladium(II) changes its reactivity dramatically: electron density is drawn towards the metal and away from the π orbitals of the alkene. This leads to activation towards attack by nucleophiles, just as in conjugate addition, and unusual chemistry follows. Unusual, that is, for the alkene; the palladium centre behaves exactly as expected.

\[
\begin{align*}
R &= \text{alkene} \\
\text{PdCl}_2 &= \text{palladium(II) chloride} \\
\text{Nu} &= \text{nucleophile} \\
\text{Cl} &= \text{chloride ion} \\
\end{align*}
\]

Many nucleophiles, such as water, alcohols, and carboxylates, are compatible with an alkene–Pd(II) complex and can attack the complexed alkene from the side opposite the palladium. The attack of the nucleophile is regioselective for the more substituted position. This parallels attack on bromonium ions but is probably governed by the need for the bulky palladium to be in the less hindered position.

\[
\begin{align*}
R \quad \text{PdCl}_2 \quad \text{Pd(II)} \quad \text{ coordination} \\
R \quad \text{Cl} \quad \text{Cl} \quad \text{Pd-L} \quad \text{Cl} \\
R \quad \text{Nu} \quad \text{Pd} \quad \text{Cl} \quad \text{nucleophilic attack} \\
R \quad \text{Cl} \quad \text{L} \quad \text{Cl} \quad \text{Pd(II)} \\
\end{align*}
\]

The resulting Pd(II) σ-alkyl species decomposes by β-hydride elimination to reveal the substituted alkene. Reductive elimination of a proton and the leaving group, usually chloride, leads to palladium(0). The weakness of this reaction is that the catalytic cycle is not complete: Pd(II), not Pd(0), is needed to complex the next alkene.

\[
\begin{align*}
\text{Nu} \quad \text{product} \\
\text{PdCl}_2 \quad \text{Pd(II)} \quad \beta\text{-hydride elimination} \\
\text{HCl} \quad \text{HCl} \quad \text{reductive elimination} \\
\text{PdL}_2 \quad \text{Pd(II)} \quad \text{CuCl}_2 \quad \text{CuCl}_2 \\
\text{O} \quad \text{O} \quad \text{CuCl}_2 \\
\end{align*}
\]

There are two solutions to this problem. We could use stoichiometric Pd(II) but this is acceptable only if the product is very valuable or the reaction is performed on a small scale. It is better to use an external oxidant to return the palladium to the Pd(II) oxidation state so that the cycle can continue. Air alone does not react fast enough (even though Pd(0) must be protected from air to avoid oxidation) but, in combination with copper(II) chloride, oxygen completes the catalytic cycle. \(\text{CuCl}_2\) oxidizes Pd(0) to Pd(II) and is itself oxidized back to Cu(II) by oxygen, ready to oxidize more palladium.

**Oxypalladation and the Wacker oxidation**

This combination of reagents has been used to oxidize terminal vinyl groups to methyl ketones and is known as the **Wacker oxidation**. The nucleophile is simply water, which attacks the activated alkene at the more substituted end in an oxypalladation step. β-Hydride elimination from the resulting σ-alkyl palladium complex releases the enol, which is rapidly converted into the more stable keto form. Overall, the reaction is a hydration of a terminal alkene that can tolerate a range of functional groups.
A related reaction is the oxidation of silyl enol ethers to enones. This requires stoichiometric palladium(II), although reoxidation of Pd(0) with benzoquinone can cut that down to about half an equivalent. The reaction provides a valuable way of turning regioselective methods for making silyl enol ethers (Chapter 20) into regioselective methods for oxidizing ketones to enones. The first step is again oxypalladation and β elimination puts the alkene in conjugation with the ketone: there are no β hydrogens on the other side.

![Diagram](image)

An example of catalytic oxypalladation is the rearrangement of allylic acetates with Pd(II). The reaction starts with oxypalladation of the alkene and it is the acetate already present in the molecule that provides the nucleophile to attack the alkene. The intermediate can reverse the oxypalladation in either direction and the product is whichever allylic acetate has the more substituted alkene. In this case, trisubstituted beats monosubstituted easily.

![Diagram](image)

The reaction is $E$-selective, which means that a simple synthesis of an $E,Z$-diene is possible from the symmetrical acetate with two $Z$-allylic alkenes. The one that rearranges goes $E$ and the one that stays behind remains $Z$. The driving force for this rearrangement, from one disubstituted alkene to another, is establishment of conjugation.

![Diagram](image)

**Alcohols and amines as intramolecular nucleophiles**

Cyclic ethers and amines can be formed with an intramolecular alcohol or amine nucleophile. Stoichiometric palladium can be avoided by using benzoquinone as the stoichiometric oxidant with a catalytic amount of palladium. In this example intramolecular oxypalladation of a diene is followed by attack of an external nucleophile on a π-allyl complex.

![Diagram](image)

Palladium coordinates to one face of the diene, promoting intramolecular attack by the alcohol on the opposite face. The resulting π-allyl palladium can form a π-allyl complex with the palladium on the lower face simply by sliding along to interact with the double bond. Nucleophilic attack of chloride from the lithium salt then proceeds in the usual way on the face opposite palladium. The overall addition to the diene is therefore $cis$. 

![Diagram](image)
Nitrogen nucleophiles also attack alkenes activated by Pd(II), and benzoquinone can again act as a reoxidant, allowing the use of catalytic quantities of palladium. The mechanism follows the same pattern as for oxygen nucleophiles, and a final isomerization produces the most stable regioisomer of product. In this example the product is an aromatic indole, so the double bond migrates into the five-membered ring.

If the substrate lacks a hydrogen suitable for β elimination and there is another alkene present in the molecule, the σ-alkyl palladium intermediate can follow the Heck pathway to form a bicyclic structure in a tandem reaction sequence. Once again, the final step is a palladium-hydride-mediated isomerization to give the endocyclic alkene.

**Palladium catalysis in the total synthesis of a natural alkaloid**

We take our leave of palladium by presenting a synthesis of an alkaloid, N-acetyl clavicipitic acid methyl ester, by Hegedus. The power of organometallic chemistry is illustrated in five of the steps in this seven-step process (the metals are highlighted in orange). Each of the organometallic steps catalysed by Pd(0) or Pd(II) has been described in this chapter. The overall yield is 18%, a remarkably good result for a molecule of such complexity.

The first step is to make an indole by Pd(II)-catalysed cyclization in the presence of benzoquinone as reoxidant. The nucleophilic nature of the 3-position of the indole (Chapter 30) was exploited to introduce the required iodide functionality. Rather than direct iodination, a high-yielding two-step procedure involving mercuration followed by iodination was employed.

Aryl iodides are more reactive towards oxidative addition than aryl bromides, and a selective Heck coupling (without phosphine ligands) with an unsaturated side chain left the bromide in place. A second Heck reaction of this bromide with an allylic alcohol was used to introduce a second side chain. Cyclization of the amide on to the allylic alcohol was achieved with palladium catalysis, not as might have been expected with palladium(0) but instead with palladium(II), to produce the seven-membered ring. Finally, the conjugated double bond was reduced and the sulfonamide removed under photolytic conditions.
An overview of some other transition metals

Some metals—palladium chief among them—see continual service in catalysis but others have their day and then fall out of favour when better alternatives become available. Tin is less popular now than it was 20 years ago because of its toxicity. A more serious case is mercury. Mercury(II) is an excellent catalyst for the addition of water to alkynes. But mercury is very toxic indeed, and the last ten years have seen its role largely superseded by gold. Do not recoil at the expense! Gold is expensive on the scale used to make rings, plates, medals, and coins, but here it is used in only catalytic quantities. Gold is in fact less expensive than palladium, rhodium, or ruthenium. Part of the age-old appeal of gold is its unreactivity as a metal: it is very stable but it does form Au(I) and Au(III) salts such as AuCl and AuCl₃. Both are available commercially and are generally used as their phosphine complexes.

Gold: activating alkynes

Au(I) and Au(III) form cationic \( \pi \) complexes with alkynes and these react with nucleophiles of many kinds. With water the result is simple: it adds to the more substituted end of the alkyne and the net result is hydration to give a ketone.

Ruthenium: alkene (olefin) metathesis

The theme of this chapter is that transition metals let you do things to organic molecules which are unthinkable without them. Nowhere is this more true than in metathesis reactions, and we finish the chapter with a reminder of the power of the ruthenium catalysts we introduced in Chapter 38. There we discussed the carbene-based mechanism of the reaction, and we showed you some simple examples such as this cyclization of a symmetrical amine to give a five-membered heterocycle using a catalytic amount of the ruthenium complex known as Grubbs I catalyst.
The synthesis of a sleep-inducing drug by GlaxoSmithKline in their laboratories at Verona used a very similar metathesis, although on an unsymmetrical amine and giving a six-membered heterocycle. The starting material is also a single enantiomer and the stereochemistry is important as the cyclopropane, introduced by a Simmons–Smith reaction (Chapter 38), must be on the opposite face of the six-membered ring to the side chain.

At another GlaxoSmithKline site, in the USA, the development of a drug for osteoporosis and osteoarthritis required a seven-membered heterocycle with two controlled chiral centres. This time the Hoveyda–Grubbs catalyst had to be used but the loading is very low indeed. Notice also that a free OH group does not interfere.

Our third example comes from Syngenta’s crop protection laboratory in Basel. It is another cyclization but this time to form an oxygen heterocycle with four chiral centres. The final product of this synthesis is malayamycin A, a natural fungicide found in bacteria. The metathesis step is early in the synthesis and you will notice that the alkene formed in this cyclization is used to provide two more chiral centres in malayamycin.

In the next chapter you will see more ways in which ruthenium—along with osmium, titanium, rhodium, and others—can be used to solve the challenges of synthesis as we look at ways of making molecules as single enantiomers.

*Organic Syntheses* are a good source of ways to make reagents and ways to carry out reactions. Comins’ reagent is featured in *Organic Syntheses*, 1997, 74, 77.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Asymmetric synthesis

Nature is asymmetric

‘How would you like to live in Looking-glass House, Kitty? I wonder if they’d give you milk in there? Perhaps looking-glass milk isn’t good to drink…’ Lewis Carroll, Through the looking-glass and what Alice found there, Macmillan, 1872.

You are chiral, and so are Alice, Kitty, and all living organisms. You may think you look fairly symmetrical in a looking-glass, but as you read this book you are probably turning the pages with your right hand and processing the information with the left side of your brain. Some organisms are rather more obviously chiral: snails, for example, carry shells that could spiral to the left or to the right. Not only is nature chiral, but by and large it exists as just one enantiomer—although some snail shells spiral to the left, the vast majority of marine snail shells spiral to the right; humans have their stomach on their left and their liver on their right; honeysuckle (Lonicera) climbs by spiralling to the left and all bindweed (Convolvulus) spirals to the right.

Nature has a left and a right, and it can tell the difference between them. You may think that human beings are sadly lacking in this respect, since as children we all had to learn, rather laboriously, which is which. Yet at an even earlier age, you could no doubt distinguish the smell of oranges from the smell of lemons, even though this is an achievement at least as remarkable as getting the right shoe on the right foot. The smells of orange and lemon differ in being the left- and right-handed versions of the same molecule, limonene. \((R)-(+)\)-Limonene smells rounded and orangey; \((S)-(−)\)-limonene is sharp and lemony. Similarly, spearmint and caraway seeds smell quite different, although again this pair of aromas differs only in being the enantiomeric forms of the ketone carvone. Evolution has left many of us regrettably sensitive to \((+)-\)androstenone, the smell of stale human urine. \((−)-\)Androstenone is essentially odourless.

‘L’univers est dissymétrique’.
Louis Pasteur, Comptes Rendus Acad. Sci., Paris June 1, 1874.

This chapter builds on the concepts introduced in Chapter 14: make sure you understand all the terms used to describe stereochemistry that are defined there. In particular make sure you are absolutely clear on the meanings of chiral, achiral, enantiomer, and diastereoisomer, along with what the designators \(R\), \(S\), \(+\), \(−\), \(L\), and \(D\) refer to.
Even bacteria know their right from their left: *Pseudomonas putida* can use aromatic hydrocarbons as a foodstuff, degrading them to diols. The diol produced from bromobenzene is formed as one enantiomer only.

How can this be? We said in Chapter 14 that enantiomers are chemically identical, so how is it that we can distinguish them with our noses and bacteria can produce them selectively? Well, the answer lies in a proviso to our assumption about the identity of enantiomers: they are identical *until they are placed in a chiral environment*. This concept will underlie all we say in this chapter about how to make single enantiomers in the laboratory. We take our lead from nature: all life is chiral, so all living systems are chiral environments.

The sheer complexity of life means that nature has to build its living structures from molecules that are chiral, principally amino acids and sugars. For all of those chiral molecules, evolution has forced the use of a single enantiomeric form, for example every amino acid in your body has the same configuration (usually labelled S). From this fact derives the larger-scale chirality of all living structures, from the right-handed double helix of DNA to the location of a blue whale’s internal organs. The answer to the question posed by Alice at the start of the chapter is most certainly no—her kitten’s digestive system will be able to hydrolyse the achiral fats in the looking-glass milk quite easily (achiral compounds are superimposable on their mirror image), but looking-glass proteins (which will be made of d-amino acids) and l-lactose will be quite indigestible.

For a perfumer or flavour and fragrance manufacturer, the distinction between the differently scented enantiomers of the same molecule is clearly of great importance. Nonetheless, we could all get by with caraway-flavoured toothpaste. Yet when it comes to drug molecules, making the right enantiomer can be a matter of life and death. Parkinson’s disease sufferers are treated with the non-proteinogenic amino acid dopa (3-(3,4-dihydroxyphenyl)alanine). Dopa is chiral, and only (S)-dopa (known as l-dopa) is effective in restoring nerve function. (R)-Dopa is not only ineffective, it is quite toxic, so the drug must be marketed as a single enantiomer.

(+)-Androstenone is also a pig pheromone. You may not wish to know that it is the active component of DuPont’s Boarmate, used by pig farmers to prepare sows for artificial insemination.

---

The molecules of life are examined in detail in the next chapter.

### Natural l-amino acids all look like this:

All have S stereochemistry except cysteine (R=SH), where the priority rules mean the chiral centre is R. Some bacteria make their cell walls from ‘unnatural’ R-amino acids to make them unassailable by the (S-amino acid-derived) enzymes used by higher organisms to hydrolyse peptides (see p. 1141).
In other cases, only one of the two enantiomers of a drug molecule possesses activity: the antidepressant citalopram and the painkiller naproxen are both marketed only as their $S$ enantiomer because the $R$ enantiomers are essentially inactive. In a few cases, the enantiomers both have activity, but in different ways: (+)-Darvon and (-)-Novrad are a painkiller and a cough suppressant, respectively.

It is not only drugs that have to be manufactured enantiomerically pure. This simple lactone is the pheromone released by the Japanese beetle *Popilia japonica* as a means of communication. The beetles, whose larvae are serious crop pests, are attracted by the pheromone, and synthetic pheromone is marketed as ‘Japonilure’ to bait beetle traps. Provided the synthetic pheromone is the stereoisomer shown, with the $Z$ double bond and the $R$ configuration at the stereogenic centre, only 25 μg per trap catches thousands of beetles. You met this compound in Chapter 27, where we pointed out that double bond stereocontrol is important since the $E$ isomer of the pheromone is virtually useless as a bait (it retains only about 10% of the activity). Even more important is control over the configuration at the chiral centre because the $S$ enantiomer of the pheromone is not only inactive in attracting the beetles, but acts as a powerful inhibitor of the $R$ enantiomer—even 1% of $S$ enantiomer in a sample of pheromone destroys the activity.

So you see why chemists need to be able to make compounds as single enantiomers. In Chapters 32 and 33 we looked at *relative* stereochemistry and how to control it; this chapter is about how to control *absolute* stereochemistry. We call this asymmetric synthesis.

In the last 25 years or so, this subject has occupied more organic chemists than possibly any other, and we are now at a point where it is not only possible (and in fact essential because of strict regulatory rules) to make many drug molecules as single enantiomers, but it is also even possible to make many chiral molecules that are indigenous to nature more cheaply in the laboratory. By 2007, for example, at least 30% of the world’s supply of menthol was not extracted from plants but made synthetically. A thousand tonnes of (-)-menthol a year is made by the company Takasago in Japan using the techniques of asymmetric synthesis that you will meet later in this chapter.

**The chiral pool: Nature’s chiral centres ‘off the shelf’**

When we first introduced you to enantiomers and chirality in Chapter 14, we stressed that any imbalance in enantiomers always derives ultimately from nature. A laboratory synthesis of a chiral compound from achiral or racemic starting materials alone always gives a racemic mixture of enantiomers. If you want to make just one enantiomer, you have to use a starting material or reagent which is also just one enantiomer. This seems like a chicken-and-egg situation, until you realize that nature provides a collection of ‘off the shelf’ enantiomerically pure compounds that we can exploit in various ways. This collection of natural, enantiomerically pure compounds is called the chiral pool. The principal groups of compounds in the chiral pool are:

1. The amino acids. There is a full list of the natural amino acids found in proteins on p. 554, but for the purposes of this chapter you should make sure you are familiar with the structures below. They all have simple side chains that are simple alkyl groups or functionalized chains with plenty of versatile chemistry, and can be obtained by hydrolysis of protein.
2. Simple derivatives of the amino acids: amino alcohols and hydroxy acids. It's easy to reduce amino acids to amino alcohols with borane (BH$_3$), usually generated in the reaction mixture by treating sodium borohydride with concentrated sulfuric acid. We will use a number of naturally derived amino alcohols as starting materials in this chapter.

\[
\begin{align*}
\text{Ph} & \quad \text{CO}_2\text{H} \\
\text{NH}_2 & \quad \text{Ph} \\
\text{OH} & \quad \text{NHMe}
\end{align*}
\]

Ephedrine is an amino alcohol which is itself a useful member of the chiral pool—it’s a plant extract readily available as either diastereoisomer (see p. 314), each, unusually, also available as either enantiomer.

It's also easy to make hydroxy acids from amino acids by diazotization. You saw this being done in Chapter 33, but as a reminder nitrous acid generates a diazonium salt, which undergoes substitution by water via an intermediate α-lactone. Two configurational inversions are involved, so the product alcohol retains $S$ stereochemistry.

\[
\begin{align*}
\text{CO}_2\text{H} & \quad \text{NH}_2 \\
\text{OH} & \quad \text{Ph} \\
\text{H}_2\text{O} & \quad \text{H}_2\text{O}
\end{align*}
\]

Some hydroxy acids are themselves available from nature, and are therefore also members of the chiral pool: both ($R$)- and ($S$)-lactic acid, for example, can be made by bacterial fermentation; mandelic, malic, and tartaric acids are extracted from almonds, apples, and grapes, respectively.

3. Carbohydrates and their derivatives. There are a great many simple carbohydrates available, but one of the most useful is mannose. Reduction to the alcohol gives the $C_2$-symmetric compound mannitol, which can be converted to a useful aldehyde by selective protection as a bis-acetal with acetone and a Lewis acid. Cleavage of the remaining diol with sodium periodate gives two equivalents of a useful protected form of glyceraldehyde.

\[
\begin{align*}
\text{OH} & \quad \text{OH} \\
\text{CHO} & \quad \text{CHO} \\
\text{O} & \quad \text{O}
\end{align*}
\]

In this chapter we will show you the many and varied ways in which members of the chiral pool can be put to work in asymmetric synthesis, but the most straightforward application is simply to spot that a target molecule has a close structural similarity with, say, an amino
acid. This is what Mori did when he made another important insect pheromone, ipsenol. The left-hand half of the molecule has the same structure as the side chain of leucine, and the $S$ chiral centre can also come from ($S$)-leucine.

![structural similarity with leucine](image)

Mori used ($S$)-leucine as the starting material and converted it to the ($S$)-hydroxy acid by the method on p. 875. The hydroxyl group was protected as the THP derivative (Chapter 23).

Reduction of the acid, via the ester, then allowed introduction of the tosylate leaving group, which was displaced to make an epoxide. The epoxide was opened by a Grignard reagent to introduce the diene portion and give the target molecule.

![This drawback is highlighted in the synthesis of oseltamivir in Chapter 43 (p. 1174).](image)

![Resolution can be used to separate enantiomers](image)

This might seem rather long-winded, and long-windedness can be a drawback of syntheses starting from the chiral pool: you have to shoe-horn your synthetic route into the available starting materials. Another drawback of syntheses starting from the chiral pool is the fact that many natural compounds are only available as one enantiomer or, if both enantiomers are available, one is much more expensive than the other. You will see some ingenious ways of circumventing this problem later in the chapter, but we deal with a very simple one in the next section.

In Chapter 14 we introduced you to resolution as a means of separating enantiomers. Resolution requires an enantiomerically pure resolving agent, which must be a compound from the chiral pool or a simple derivative of that compound. When the Swiss company Cilag wanted one enantiomer of the unusual chiral amino acid in the margin in order to make some potential drug candidates, the chemists there decided the easiest way to get hold of it quickly and in large quantities was to make it in racemic form and then resolve it. It turned out that one of the two enantiomers of the protected derivative below forms a crystalline salt with cheap, readily available (–)-ephedrine, while the other remains in solution. Filtration and treatment with acid to remove the protecting group and protonate the acid gave them a single enantiomer of their target amino acid.
Of course, with resolution, there is a maximum yield of 50% because if you only want one enantiomer, the other is wasted. But there are many cases where you might want both enantiomers. You may need to test them both for biological activity, for example. In that case, resolution is ideal—in the example above the chemists at Cilag could get hold of the other enantiomer of the amino acid just by evaporating the mother liquors from the recrystallization. This is a big advantage of resolution: it lets you get both enantiomers using just one compound from the chiral pool.

**Chiral auxiliaries**

In Chapter 33 we showed you methods for making single diastereoisomers using diastereoselective reactions. Diastereoselective reactions work just as well whether the starting material is racemic or enantiomerically pure—you get the same diastereoisomeric outcome in each case, but if you start with racemic material you get racemic product and if you start with enantiomerically pure material you get enantiomerically pure product. Here’s an example, from p. 867:

So if you use a starting material from the chiral pool, you can build new chiral centres in enantiomerically pure form just by using diastereoselective reactions. We showed you two syntheses at the end of Chapter 33 using this idea: the chiral pool starting materials (S)-lactic acid and (S)-serine were converted to two natural products using a series of diastereoselective reactions to introduce further chiral centres into the molecules.

The syntheses rely on the fact that the structure of the chiral pool starting material is still there in the product. But the same idea can work even if the starting chiral compound is no longer part of the target you are making. In this case the chiral starting material is called a chiral auxiliary. Chiral auxiliaries are extremely versatile because they can be used to make a whole variety of target molecules in enantiomerically pure form. We will explain how they work with two examples.
The product of a Diels–Alder reaction between cyclopentadiene and benzyl acrylate must necessarily be racemic as both reagents are achiral. Although only one diastereoisomer—the *endo* product—is formed, it must be formed as an exactly 50:50 mixture of *enantiomers*. There is nothing to tell the diene whether to attack the top or the bottom face of the dienophile so it does both, each 50% of the time.

\[
\text{BnOH} + \text{Cl} \rightarrow \text{OBn} \quad \text{achiral diene} \quad + \quad \text{achiral dienophile}
\]

\[
\text{attack on top or bottom face of dienophile equally likely}
\]

\[
\text{must form as a 50:50 mixture of two enantiomers}
\]

Now see what happens if we replace the achiral benzyl ester group of the dienophile with an amide derived from the amino acid valine. Here's the synthesis of such a dienophile using the amino acid reduction you saw on p. 1105.

\[
\text{Me}_{2}S.BH_{3} \quad (S)-\text{valine} \\
\text{Cl} \quad \rightarrow \quad \text{HN} \quad \text{EtO} \quad \text{EtO} \quad \text{K}_{2}\text{CO}_{3} \quad 1. \text{NaH} \quad 2. \text{OEt}
\]

The two faces of the double bond of the dienophile are now different because of the chiral centre: they are diastereotopic, and the diene can distinguish between them. If we now do the Diels–Alder reaction in the presence of a Lewis acid, Et_{2}AlCl, the aluminium chelates the oxygen atoms of the dienophile to form the rigid and reactive structure shown below. The isopropyl group is held in such a way that its steric bulk prevents the diene attacking that face of the prochiral alkene. The diene has no choice but to attack from above, and only one of the possible diastereoisomeric products is formed.

We call the green valine-derived part of this molecule the *chiral auxiliary*—it assists the substrate to react in a diastereoselective way such that only one of the two possible products is allowed to form. The chiral auxiliary was enantiomerically pure to start with, so the product must be diastereoisomerically *and* enantiomerically pure.

Finally comes the step which shows the power of chiral auxiliary strategy: we just remove the chiral auxiliary from the product by treating with a nucleophile. The auxiliary can in principle be used again, but most importantly of all, the product obtained is just one of the two enantiomers we made in the racemic version of this reaction. This isn't a resolution—all...
of these steps go in high yield—it is truly an enantioselective synthesis of the Diels–Alder product, using a chiral auxiliary to help us.

Overall, by sequential attachment of the auxiliary, diastereoselective reaction, and removal of the auxiliary we have made the same product but as a single enantiomer.

---

**This is what we mean by a chiral auxiliary strategy**

1. An enantiomerically pure compound (usually derived from a simple natural product like an amino acid), called a chiral auxiliary, is attached to the starting material.
2. A diastereoselective reaction is carried out, which, because of the enantiomeric purity of the chiral auxiliary, gives only one enantiomer of the product.
3. The chiral auxiliary is removed by, for example, hydrolysis, leaving the product of the reaction as a single enantiomer. The best chiral auxiliaries (of which the example above is one) can be recycled, so although stoichiometric quantities are needed, there is no waste.

We have introduced you to this chiral auxiliary before any other because it is more commonly used than any other. It is a member of the oxazolidinone (the name of the heterocyclic ring) family of auxiliaries developed by David Evans at Harvard University, and is easily and cheaply made from the amino acid (S)-valine. Even though it is cheap, it can be recycled. The last step of the route above regenerates the auxiliary ready for re-use.

The most versatile chiral auxiliaries should also be available as both enantiomers. For the valine-derived one here, this is not the case—(R)-valine is quite expensive since it is not found in nature. However, by starting with the naturally occurring (and cheap) compound nor-ephedrine, we can make an auxiliary that, although not enantiomeric with the one derived from (S)-valine, acts as though it were.

As the diagram shows, the two substituents of the auxiliary lie on the top face of the dienophile and force the cyclopentadiene this time to attack the bottom face. Now when the auxiliary is cleaved from the product the opposite enantiomer is formed. We can choose which enantiomer we want simply by choosing the right auxiliary for the job.

**Alkylation of enolates**

Chiral auxiliaries can be used in plenty of other reactions, and some of the most common are reactions of enolates. Evans’s oxazolidinone auxiliaries are particularly appropriate here.

---

Enolates are a sort of alkene and can form as cis or trans geometrical isomers. One of the consequences of this is discussed in Chapter 33.
because they are readily turned into enolizable carboxylic acid derivatives. Treatment with
base (usually LDA) at low temperature produces an enolate, the bulky auxiliary means that
only the cis enolate forms: the trans enolate is too hindered.

Coordination of the lithium ion to the other carbonyl oxygen makes the whole structure
rigid, fixing the isopropyl group round the back of the molecule, where it can provide
maximum hindrance to attack on the ‘wrong’ face of the enolate. Electrophiles have little
choice but to attack the enolate from the front, and the table shows the ratio of diastereo-
isomers (the diastereoisomeric ratio, abbreviated to d.r.) produced for a selection of alkylating
agents.

As you can see, none of these reactions is truly 100% diastereoselective and, indeed, only
the best chiral auxiliaries (of which this is certainly one) give >98% of a single diastereoiso-
er. The problem with less than perfect diastereoselectivity is that, when the chiral auxiliary
is removed, the final product is contaminated with some of the other enantiomer. A 94:6 ratio
of diastereoisomers will result in a 94:6 ratio of enantiomers, or a sample of 94:6 e.r. (e.r. for
enantiomeric ratio).

Enantiomeric excess
Compounds that are neither racemic nor enantiomerically pure are usually called enantio-
merically enriched. Chemists have two ways of referring to the ratio of enantiomers in an
enantiomerically enriched sample. The first is the simple one we have just used: e.r. or enan-
tiomer ratio, expressed as two numbers adding to 100. More common, however, is to
express this ratio as an enantiomeric excess. Enantiomeric excess (or ee) is defined as the excess
of one enantiomer over the other, expressed as a percentage of the whole. So a 94:6 mixture
of enantiomers consists of one enantiomer in 88% excess over the other, and we call it an
enantiomerically enriched mixture with 88% ee. Why not just say that we have 94% of one
enantiomer? Enantiomers are not like other isomers because they are simply mirror images.
The 6% of the minor enantiomer can be paired with 6% of the major isomer to form a race-
mic mixture amounting to 12% of the total. The mixture contains 12% racemate and 88% of
one enantiomer, hence 88% ee.
We will see shortly how we can make further use of the chiral auxiliary to increase the ee of the reaction products. But first, we should consider how to measure ee. One way is simply to measure the angle through which the sample rotates plane-polarized light. The angle of rotation is approximately proportional to the enantiomeric excess of the sample (see box). The problem with this method is that to measure an actual value for ee you need to know what rotation a sample of 100% ee gives, and that is not always possible. Also, polarimeter measurements are notoriously unreliable—they depend on temperature, solvent, and concentration, and are subject to massive error due to small amounts of highly optically active impurities.

**Is optical rotation proportional to enantiomeric excess?**

Imagine you have a sample, A, of an enantiomerically pure compound—a natural product perhaps—and, using a polarimeter, you find that it has an \([\alpha]_D\) of +10.0. Another sample, B, of the same compound, which you know to be chemically pure (perhaps it is a synthetic sample), shows an \([\alpha]_D\) of +8.0. What is its enantiomeric excess? Well, you would have got the same value of 8.0 for the \([\alpha]_D\) of B if you had mixed 80% of your enantiomerically pure sample A with 20% of a racemic (or achiral) compound with no optical rotation. Since you know that sample B is chemically pure, and is the same compound as A, it must therefore indeed consist of 80% enantiomerically pure material plus 20% racemic material, or 80% of one enantiomer plus 20% of a 1:1 mixture of the two enantiomers—which is the same as 90% of one enantiomer and 10% of the other, or 80% enantiomeric excess. Optical rotations can give a guide to enantiomeric excess—sometimes called optical purity in this context—but slight impurities of compounds with large rotations can distort the result and there are some examples where the linear relationship between ee and optical rotation fails because of what is known as the Horeau effect. You can read more about this in Eliel and Wilen, Stereochemistry of organic compounds, Wiley, 1994.

Chemists now usually use chromatography, or occasionally spectroscopy, to quantify ratios of enantiomers. You may think that this should be impossible—since enantiomers are chemically identical and have identical NMR spectra, how can chromatography or spectroscopy tell them apart? Well, again, they are identical unless they are in a chiral environment. We introduced HPLC on a chiral stationary phase as a way of separating enantiomers preparatively in Chapter 14. The same method can be used analytically—less than a milligram of chiral compound can be passed down a narrow column containing silica modified which a chiral additive. One enantiomer passes through the silica faster than the other; the two enantiomers are separated and the quantity of each can be measured (usually by UV absorption or by refractive index changes) and an ee derived. Gas chromatography can be used in the same way—the columns are packed with a chiral stationary phase such as the isoleucine derivative shown in the margin.

Distinguishing enantiomers spectroscopically relies again on putting them into a chiral environment. One way of doing this, if the compound is, say, an alcohol or an amine, is to make a derivative (an ester or an amide) with an enantiomerically pure and racemization-proof acyl chloride. The one most commonly used is known as Mosher’s acyl chloride, after its inventor Harry Mosher, although there are many others. The two enantiomers of the alcohol or amine now become diastereoisomeric esters, and give different sets of peaks in the NMR spectrum—the integrals can be used to determine ee and, although the \(^1\)H NMR of such a mixture of diastereoisomers may become quite cluttered because it is a mixture, the presence of the CF₃ group means that the ratio can alternatively be measured by integrating the two singlets in the otherwise featureless plain of the \(^19\)F NMR spectrum.

Another powerful method of discriminating between enantiomers is to add an enantiomerically pure compound to the NMR sample that simply forms a complex with the compound under investigation. The complexes formed from the two opposite enantiomers are diastereoisomeric, and therefore have different chemical shifts and, by integrating the NMR signals, the ratio of enantiomers can be determined. Among the most commonly used is this alcohol, 2,2,2-trifluoro-1-(9-anthryl)ethanol, or TFAE, which can both hydrogen-bond to and form...
π-stacked complexes with a range of functionalized compounds, and often splits NMR signals due to enantiomeric compounds very cleanly.

Time to go back to chiral auxiliaries. We pointed out that, although we want to get maximum levels of stereoselectivity in our chiral-auxiliary-controlled reaction, we may still have a small percentage of a minor diastereoisomer, which, once we have removed our chiral auxiliary, will compromise the ee of our final product. It is at this point that we can use a trick that essentially employs the chiral auxiliary in a secondary role as a resolving agent. Provided the products are crystalline, it will usually be possible to recrystallize our 94:6 mixture of diastereoisomers to give essentially a single diastereoisomer, rather like carrying out a resolution with an enormous head start. Once this has been done, the chiral auxiliary can be removed and the product may be very close to 100% ee. Of course, the recrystallization sacrifices a few percentage points of yield, but these are invariably much less valuable than the few percentage points of ee gained! Here is an example from the work of Evans himself. During his synthesis of the complex antibiotic X-206 he needed large quantities of the small molecule below. He decided to make it by a chiral-auxiliary-controlled allylation, followed by reduction to give the alcohol. The auxiliary needed is the one derived from norephedrine, and the reaction of the enolate with allyl iodide gives a 98:2 mixture of diastereoisomers. However, recrystallization converts this into an 83% yield of a single diastereoisomer in >99% purity, giving material of essentially 100% ee after removal of the auxiliary.

This is one big bonus of using a chiral auxiliary—it’s much easier to purify diastereoisomers than enantiomers and a chiral auxiliary-controlled reaction necessarily produces diastereoisomeric products.

Both these examples of auxiliary-controlled alkylation make use of LiAlH₄ reduction to the alcohol in the step which removes the auxiliary. You saw attack with an alkoxide above, and several other alternative methods are possible as well, summarized below. DIBAL (i-Bu₂AlH, p. 533) reduces the product to an aldehyde, while converting the product to a Weinreb amide (p. 219) makes formation of a ketone possible.

Simple hydrolysis under acid or basic conditions risks epimerizing the newly created chiral centre, and a good solution is to use the less basic, more nucleophilic hydroperoxide anion. This was the approach taken by chemists making this component of a collagenase inhibitor. Notice that this auxiliary is a variant based on l-phenylalanine.
These various ways of removing auxiliaries illustrate the ways in which it is possible to make a virtue out of one of their big disadvantages: chiral auxiliaries must first be attached to the compound under construction, and after they have done their job they must be removed. The best auxiliaries can be recycled, but even then there are still at least two ‘unproductive’ steps in the synthesis.

**Oxazolidinones are not the only auxiliaries**

Other auxiliaries are also used, and the choice of auxiliary may depend not only on the selectivity of the reaction under investigation but also on the physical properties of the products. The camphor-based auxiliary of Oppolzer is reputed to confer crystallinity on its derivatives, while the pseudoephedrine auxiliary of Myers is cheap, readily available, and very easy to introduce. More bulky auxiliaries such as 8-phenylmenthol work well where control over long-range interactions, such as conjugate additions, are required.

**Chiral reagents**

A chiral auxiliary is a chiral molecule attached to the starting material of the reaction; diastereoselective reactions of compounds from the chiral pool are likewise controlled by chirality in the starting material, and we call this type of stereocontrol *substrate control*. But is it also possible for enantioselective reactions to be controlled by chiral reagents. For example, a typical achiral base will just remove a proton from a substrate, but an enantiomerically pure chiral base can select one of two enantiotopic protons and form a product enantioselectively. The product of course has to be chiral, so we can’t use a chiral base to make planar enolates enantioselectively, for example, but we can a chiral base to make chiral organolithiums.

Alkylolithiums are sufficiently strong as bases to remove the protons adjacent to the nitrogen atom of N-Boc pyrrolidine, shown in the margin. The product of deprotonation is an organolithium which is a chiral molecule: the lithium-bearing carbon is chiral.

Alkylolithiums can be turned into chiral bases in quite a simple way—by complexation with a chiral ligand. A widely used example is the tetracyclic diamine (−)-sparteine. Sparteine’s structure looks complex, but it is a relatively widely available natural product which folds around the lithium atom of an alkylolithium and places the base in a chiral environment.

This chiral base can now choose to remove from the pyrrolidine substrate just one of the enantiotopic protons adjacent to nitrogen, and form a chiral, enantiomerically enriched organolithium. The stereochemistry of the organolithium is preserved through its reactions with electrophiles such as the ketone shown here.
Asymmetric catalysis

If we want to create a new chiral centre in a molecule, our starting material must have prochirality—the ability to become chiral in one simple transformation. The most common prochiral units that give rise to new chiral centres are the trigonal carbon atoms of alkenes and carbonyl groups, which become tetrahedral by addition reactions. In the last section you saw a prochiral, tetrahedral CH₂ group becoming a chiral organolithium by enantioselective removal of one enantiotopic proton. Much more common are the reactions you saw in the section before that, where in every case a prochiral alkene (we can count enolates as alkenes for this purpose) reacted selectively on one face because of the influence of the chiral auxiliary, which made the faces of the alkene diastereotopic.

Catalytic asymmetric reduction of ketones

One of the simplest transformations you could imagine of a prochiral unit into a chiral one is the reduction of a ketone. Although chiral auxiliary strategies have been used to make this type of reaction asymmetric, conceptually the simplest way of getting the product as a single enantiomer would be to use a chiral reducing agent—in other words, to attach the chiral influence not to the substrate (as we did with chiral auxiliaries) but to the reagent. We need an asymmetric version of NaBH₄.

The active reducing agent is generated when the heterocycle forms a complex with borane. Only catalytic amounts (usually about 10%) of the boron heterocycle are needed because borane is sufficiently reactive to reduce ketones only when complexed with the nitrogen atom. The rest of the borane just waits until a molecule of catalyst becomes free.

CBS reductions are best when the ketone’s two substituents are well-differentiated sterically—just as Ph and Me are in the example above. The reaction works because the heterocyclic
catalyst brings together the borane (which complexes to its basic nitrogen atom) and the carbonyl compound (which complexes to its Lewis-acidic boron atom). Complexation activates both partners towards reaction: donating electron density to the borane is essential to persuade it to transfer hydride, and withdrawing electron density from the carbonyl group makes it electrophilic enough to react with a weak hydride source. The hydride is delivered via a six-membered cyclic transition state, with the enantioselectivity arising from the preference of the larger of the ketone’s two substituents (Rl) for the pseudoequatorial position on this ring.

**Making the CBS catalyst**

To make the CBS heterocycle, (S)-proline has to be protected as its N-Cbz derivative (Chapter 23) and converted to its methyl ester. Esters react with Grignard twice to give tertiary alcohols (Chapter 10), so PhMgBr followed by deprotection gives the amino alcohol needed. Condensation with methylboronic acid (MeB(OH)2) gives the stable catalyst.

Until recently, the CBS reagent was one of the most commonly used asymmetric reducing agents for ketones. But in the early years of the 21st century a new reaction has taken over that role—one in which the job of bringing together the ketone and the reducing agent is taken by an atom of ruthenium. The ruthenium is added as Ru(II) in a 16-electron complex (see p. 1116) with an aromatic compound such as 1,3,5-trimethylbenzene (known as mesitylene). A chiral ligand is needed—the diamine derivative shown here is best. Only very small amounts (often << 1%) of the catalyst and ligand are required, which is a good thing as both are much more expensive than the reagents in the CBS reduction. The reducing agent itself can be hydrogen or, more conveniently, a more easily handled source of hydrogen atoms such as isopropanol (which gets oxidized to acetone) or formic acid (which gets oxidized to carbon dioxide). Here’s a typical example; we will explain how it works shortly.
You have met several reactions of ruthenium complexes, especially in Chapters 38 and 40, where you saw ruthenium carbenes catalysing the metathesis of alkenes. Ruthenium is one of a select group of transition metals (Pd, Ru, Rh, Cu, Os, and Ti being the others) which play an important role in asymmetric catalysis. The key to their success is the transition metal coordination chemistry we looked at in the last chapter: the metals can act as coordination sites for substrates, and by using other ligands which are chiral and enantiomerically pure, the reactions they catalyse can be made to take place in an asymmetric environment.

The ruthenium-catalysed reduction of ketones starts with coordination of the tosyl-diamine ligand ((S,S)-N-toluenesulfonyl 1,2-phenylenediamine, or ‘TsDPEN’) to the ruthenium metal. This is a 16-electron complex, and can be reduced by formic acid to an 18-electron ruthenium hydride.

\[
\text{RuCl}_2 \text{PhPhNNTs} \rightarrow \text{H}_2\text{NNTs} \text{RuPhPh} + \text{CO}_2
\]

Now comes the reduction. Provided the ketone approaches the ruthenium complex in the right orientation, with the smaller methyl group tucked in under the ruthenium and the larger aryl group pointing away from the bulky ligands, the 18e complex can transfer hydrogen atoms simultaneously: **H**⁻ from Ru and **H**⁺ from the protonated nitrogen. The chiral ligand means that the alcohol is formed as a single enantiomer, and the ruthenium catalyst is regenerated.

\[
\text{RuCl}_2 \text{PhPhNNTs} + \text{CMe}_3\text{CHCO}_2\text{H} \rightarrow \text{RuCl}_2 \text{PhPhNNTs} + \text{S-enantiomer} + \text{CO}_2
\]

The reduction shown below is particularly important because it generates a late intermediate in the industrial synthesis of the anti-asthma drug montelukast (Singulair). Several methods have been used, but in 2008 chemists at the Croatian pharmaceutical company Pliva patented a method using the ruthenium catalyst with a derivative of TsDPEN as a ligand to gives the product in 83% yield and 99.8% ee on a scale of several kilograms.

\[
\text{RuCl}_2 \text{PhPhNNTs} + \text{TsDPEN ligand} \rightarrow \text{RuCl}_2 \text{PhPhNNTs} + \text{S-enantiomer} + \text{CO}_2
\]

83% yield, 99.8% ee
Two methods for reducing carbonyl compounds enantioselectively

\[

\]

Catalytic asymmetric hydrogenation of alkenes

Reduction of a ketone can give a chiral secondary alcohol, but reduction of an alkene by addition of hydrogen to one of its two enantiotopic faces can give all sorts of products, creating either one or two chiral centres, depending on the substituents on the alkene. By way of illustration (and explanation will follow soon) the alkene hydrogenation below creates, in one step, the two chiral centres of a precursor to the anti-obesity drug taranabant. A single diastereoisomer is formed by syn addition of hydrogen, and a chiral ligand ensures that one enantiomer is formed preferentially.

You have seen numerous hydrogenations of alkenes using hydrogen over a solid catalyst of palladium supported on charcoal (‘heterogeneous hydrogenation’), but catalytic asymmetric hydrogenation of alkenes uses a different type of catalyst—a soluble complex, often of Ru or Rh with phosphine-containing ligands. The substrates for asymmetric alkene hydrogenation are also more limited than those for hydrogenation with Pd/C because they must carry a functional group close to the alkene, allowing coordination to the transition metal catalyst. In the example above, that functional group is the amide directly adjacent to the alkene.

The inspiration for these catalysts came from the work of Wilkinson in London in the 1960s, who showed that RhCl(PPPh3)_3 (known as Wilkinson’s catalyst) promoted homogeneous hydrogenation of alkenes (i.e. during the reaction there is only one, solution, phase). Wilkinson’s catalyst is a 16-electron complex of Rh(I), and it works as a catalyst because it can easily lose one of the phosphine ligands to form a 14-electron complex. This undergoes addition of H2, giving a 16-electron Ru(III) complex.
The complex is still coordinatively unsaturated, so an alkene can form a π complex with a full complement of 18 electrons. Migratory insertion of one of the hydrogen atoms, followed by reductive elimination, gives back the 14-electron Rh complex and the reduced alkane.

The conceptual advance which allows this sort of hydrogenation to become asymmetric is the replacement of the two achiral triphenylphosphine ligands of Wilkinson’s catalyst with chiral phosphine ligands. Notice that two of the triphenylphosphines remain coordinated through the whole reaction mechanism, so by doing this we can ensure that the Rh always remains in a chiral environment.

The usual solution is to use one chiral molecule containing two phosphorus atoms, and the most important of these is BINAP. BINAP is a chelating diphosphine: the metal sits between the two phosphorus atoms, firmly anchored in a chiral environment. The chirality here is of an unusual sort, since BINAP, which you met in Chapter 14 (p. 319), has no chiral centres. It is one of the class of chiral molecules, known as atropisomers, whose chirality arises from the inability of the bond between the two naphthalene rings to rotate.

Incorporating (S)- or (R)-BINAP into a hydrogenation with Rh can lead to high enantiomeric excesses in the products because during the migratory insertion step the complex is forced to transfer hydrogen to only one of the two possible enantiotopic faces of the alkene. As we remarked before, asymmetric hydrogenations require a functional group which can coordinate to the metal, and with Rh the best substrates are N-acyl enamines. Those of the type shown below give excellent results, and usefully with (S)-BINAP the products are protected amino acids of the opposite enantiomeric series to those found in nature.

It is even economical for the more expensive of the natural amino acids to be made synthetically by this type of reaction rather than isolated from natural sources—phenylalanine, which is of industrial importance as a component of the artificial sweetener aspartame (NutraSweet), is manufactured using enantioselective hydrogenation.

Noyori found that using ruthenium instead of rhodium broadens greatly the scope of the substrates that will undergo asymmetric hydrogenation. They still need a functional group—usually the OH group of an alcohol or a carboxylic acid—to allow coordination to the metal, but the alkene itself can be a simple allylic alcohol or unsaturated acid derivative. BINAP is again a good ligand, and of course by choosing which enantiomer of BINAP you use you can choose which enantiomer of the product you get.
Two important industrial asymmetric syntheses which routinely use this chemistry are the production of the painkiller (S)-naproxen and the synthetic intermediate and perfumery compound (R)-citronellol. It is gratifying to note that this chemistry, using <1% of Ru, gives citronellol in higher enantiomeric purity than many natural sources of the same compound!

Reduction of unsaturated carboxylic acids gives products that you might alternatively think of making by auxiliary-controlled alkylation methods. When the NutraSweet company needed this chiral branched carboxylic acid as a single enantiomer, they initially used the auxiliary methods of p. 1110 to make a small amount, but they found that ruthenium-catalysed hydrogenation was greatly to be preferred on a large scale: just 22 g of the ruthenium-(S)-BINAP complex is needed to produce 50 kg of product with 90% ee.

In the last 20 years, the variety of ligands available for rhodium and ruthenium-catalysed hydrogenations has increased to the point where the right combination of metal and ligand will reduce almost any unsaturated carboxylic acid derivative in high enantiomeric excess. Details are beyond the scope of this book, but we leave you with four examples, all from industrial drug syntheses, to illustrate how versatile the method can be.

**Resolution of BINAP**

BINAP is not derived from a natural product, and has to be synthesized in the laboratory and resolved using a naturally derived resolving agent. The scheme shows one method by which enantiomerically pure BINAP may be made—the resolution step is unusual because it relies on formation of a molecular complex, not a salt. The bis phosphine oxide of (S)-BINAP co-crystallizes with di-O-benzoyl-L-tartrate, leaving the (R)-phosphine oxide in solution. Base releases the pure (R)-phosphine oxide that is resolved, which is then reduced to the phosphine with trichlorosilane.
Asymmetric epoxidation

Asymmetric hydrogenation of an alkene can create two new chiral centres, but introduces no new functionality as it does so. Asymmetric oxidation of an alkene is different: it can create two new chiral centres and two new functional groups at the same time. We will now look at two examples of asymmetric oxidation, both products of the laboratories of Professor Barry Sharpless.

The first of Sharpless’s reactions is an oxidation of alkenes by asymmetric epoxidation. You met vanadium as a transition-metal catalyst for epoxidation with t-butyl hydroperoxide in Chapter 32, and this new reaction makes use of titanium, as titanium tetraisopropoxide, Ti(O-i-Pr)_4, to do the same thing. Sharpless and his co-worker Tsutomu Katsuki surmised that by adding a chiral ligand to the titanium catalyst they might be able to make the reaction asymmetric. The ligand that works best is diethyl tartrate, and one example of the reaction is shown below.

Transition-metal-catalysed epoxidations work only on allylic alcohols, so this is a limitation of the method, but otherwise there are few restrictions on what can be epoxidized enantioselectively, and when this reaction was discovered in 1981 it was by far the best asymmetric reaction known. Because of its importance, a lot of work went into discovering exactly how the reaction worked, and the scheme below shows what is believed to be the active complex, formed from two titanium atoms bridged by two tartrate ligands (shown in orange). Each titanium atom retains two of its isopropoxide ligands and is coordinated to one of the carbonyl groups of the tartrate ligand. The reaction works best if the titanium and tartrate are left to stir for a while so that these dimers can form cleanly. When the oxidizing agent (t-BuOOH, shown in green) is added to the mixture, it displaces one of the remaining isopropoxide ligands and one of the tartrate carbonyl groups.

For this oxidizing complex to react with an allylic alcohol, the alcohol must become coordinated to the titanium too, displacing a further isopropoxide ligand. Because of the shape
of the complex the reactive oxygen atom of the bound hydroperoxide has to be delivered to the lower face of the alkene (as drawn), and the epoxide is formed in high enantiomeric excess. Displacement of the product by another molecule of hydroperoxide starts the cycle again.

Different allylic alcohols coordinate in the same way to the titanium and reliably present the same enantiotopic face to the bound oxidizing agent, and the preference for oxidation with 1-(-)-DET is shown in the schematic diagram below. Tartrate is ideal as a chiral ligand because it is available relatively cheaply as either enantiomer. L-tartrate is extracted from grapes; D-(–)-tartrate is rarer and more expensive, but still cheap by the standards of some of the bisphosphine ligands used in the last section. By using D-(–)-tartrate it is, of course, possible to produce the other enantiomer of the epoxide equally selectively.

Sharpless also found that this reaction works with only a catalytic amount of titanium–tartrate complex because the reaction products can be displaced from the metal centre by more of the two reagents. The catalytic version of the asymmetric epoxidation is well suited to industrial exploitation, and the American company J. T. Baker has employed it to make synthetic disparlure, the pheromone of the gypsy moth, by oxidation of the epoxy alcohol to an aldehyde with pyridinium dichromate (PDC) (p. 543), Wittig reaction (p. 689), and hydrogenation.

Not many target molecules are themselves epoxides, but the great thing about the epoxide products is that they are highly versatile—they react with many types of nucleophiles to give 1,2-disubstituted products. You met the chiral beta-blocker drug propranolol in Chapter 28, and its 1,2,3-substitution pattern makes it a good candidate for synthesis using asymmetric epoxidation.
Unfortunately, the obvious starting material, allyl alcohol itself, gives an epoxide that is hard to handle, so Sharpless, who carried out this synthesis of propranolol, used this silicon-substituted allylic alcohol instead. The hydroxyl group was mesylated and displaced with 1-naphthoxide and, after treatment with fluoride to remove the silicon, the epoxide was opened with isopropylamine.

Chemists at the drug company Wyeth needed the amine shown in the margin. The 1,2,3-functional group pattern led them to think of using the Sharpless asymmetric epoxidation, and epoxidation of a fluorinated allylic alcohol using D-(–)-diisopropyl tartrate (DIPT) gave them the enantiomer they wanted with slightly better selectivity than diethyl tartrate. The benzylic end of the epoxide is more reactive towards nucleophilic substitution, and in the presence of Ti(Oi-Pr)₄, this time simply acting as a Lewis acid, the lithiated heterocycle opens the epoxide with inversion of configuration.

Finally, it’s necessary to bring in the amino group, and this can be done by tosylation of the less hindered primary hydroxyl group selectively, closing to an epoxide in base, and then reopening the epoxide at the less hindered terminal position with methylamine.

The Sharpless asymmetric epoxidation is reliable, but it works only for allylic alcohols. There is an alternative, however, which works with simple alkenes. The method was developed by Eric Jacobsen and employs a manganese catalyst with a chiral ligand built from a simple diamine. The diamine is not a natural compound and has to be made in enantiomeric form by resolution, but at least that means that both enantiomers are readily available. The diamine is condensed with a derivative of salicylaldehyde to make a bis-imine known as a ‘salen’.

‘Salen’ is an abbreviation of salicyl ethylenediamine and simpler salens had long been used as tetridentate ligands for coordination chemistry.
Mn(III) sits neatly in a tetracoordinate pocket in the ligand, and catalyses the epoxidation of simple alkenes by sodium hypochlorite, NaOCl, ordinary domestic bleach. Best results are obtained when the alkenes are cis (although an alternative range of ligands, developed by Tsutomu Katsuki, work well with trans alkenes), and one of the most significant applications of the Jacobsen epoxidation is with indene, which gives an epoxide in 84% ee with <1% of the catalyst. The mechanism of the reaction is complex and not fully understood, although it probably involves a Mn(V) oxo species and may involve radical intermediates.

Together, the epoxidations of Sharpless, Jacobsen, and Katsuki, plus others we do not have space to cover, provide valuable solutions to many synthetic problems—in particular because epoxides are such useful reactive synthetic intermediates. But no epoxidation reaction is as general as the oxidation reaction we cover next.

**Asymmetric dihydroxylation**

This alternative asymmetric oxidation really is probably the best asymmetric reaction of all. It is an asymmetric version of the syn dihydroxylation of alkenes by osmium tetroxide. Here is an example—although the concept is quite simple, the recipe for the reactions is complicated so we need to approach it step by step.

The active reagent is based on osmium(VIII) and is used in just catalytic amounts. This means that there has to be a stoichiometric quantity of another oxidant to reoxidize the osmium after each catalytic cycle—K₃Fe(CN)₆ is most commonly used. Because OsO₄ is volatile and toxic, the osmium is usually added as K₂OsO₂(OH)₄, which forms OsO₄ in the reaction mixture. The ‘other additives’ include K₂CO₃ and methanesulfonamide (MeSO₂NH₂), which increases the rate of the reaction by regenerating the catalyst at the end of each catalytic cycle.

Now for the chiral ligand. Tertiary amines are good ligands for osmium and increase the rate of dihydroxylation: one of the reasons that NMO is used in the racemic version of the reaction (see p. 442) is that the by-product, N-methylmorpholine, accelerates the reaction. Sharpless chose some available chiral tertiary amines as ligands, and it turned out that the best ones are based on the alkaloids dihydroquinidine and dihydroquinine, whose structures are shown below. They coordinate to the osmium through the green nitrogen atom.

---

This epoxide plays a starring role in the synthesis of the anti-HIV compound indinavir: see Chapter 43.
The alkaloids (usually abbreviated to DHQD and DHQ, respectively) must be attached to an aromatic group Ar, the choice of which varies according to the substrate. The most generally applicable ligands are these two phthalazines in which each aromatic group Ar carries two alkaloid ligands, either DHQ or DHQD.

Dihydroquinine and dihydroquinidine are not enantiomeric (although the chiral centres ringed in orange are of opposite configuration in each of the pairs, those ringed in brown remain the same in both), but they act on the dihydroxylation as though they were.

Here, after all that introduction, is a real example, and probably the most remarkable of any in this chapter. \textit{trans}-Stilbene dihydroxylates more selectively than any other alkene, and this particular example is one of the most enantioselective catalytic reactions ever invented.

\begin{align*}
\text{Ph} & \quad \text{Ph} & \quad \text{OH} & \quad \text{OH} \\
\text{Ph} & \quad \text{Ph} & \quad \text{cat. K}_2\text{OsO}_2\text{(OH)}_4, K_2\text{Fe(CN)}_6, K_2\text{CO}_3, \text{MeSO}_2\text{NH}_2 & \quad t\text{-BuOH, H}_2\text{O, 0 }^\circ\text{C} & \quad \text{cat. DHQD}_2\text{PHAL} \\
\text{Ph} & \quad \text{Ph} & \quad \text{trans-stilbene} & \quad \text{cat. K}_2\text{OsO}_2\text{(OH)}_4, K_2\text{Fe(CN)}_6, K_2\text{CO}_3, \text{MeSO}_2\text{NH}_2 & \quad t\text{-BuOH, H}_2\text{O, 0 }^\circ\text{C} & \quad \text{cat. DHQ}_2\text{PHAL} \\
\end{align*}

\[99.8\% \text{ ee} \quad >99.5\% \text{ ee}\]

We can sum up the usual selectivity of the AD reaction with the diagram shown below. With the substrate arranged as shown, with the largest (R_L) and next largest (R_M) groups bottom left and top right, respectively, DHQD-based ligands will direct OsO_4 to dihydroxylate from the top face of the alkene and DHQ-based ligands the bottom face.

\begin{itemize}
  \item \textbf{Enantioselectivity in the Sharpless asymmetric dihydroxylation}
\end{itemize}

The reason for this must come from the way in which the substrate interacts with the osmium–ligand complex. However, the detailed mechanism of the asymmetric dihydroxylation is still far from clear-cut. What is known is that the ligand forms some sort of ‘chiral pocket’, like an enzyme active site, with the osmium sitting at the bottom of it. Alkenes can only approach the osmium if they are correctly aligned in the chiral pocket, and steric hindrance forces the alignment shown in the scheme above. The analogy with an enzyme active
site goes even further, since it appears that part of the pocket is ‘attractive’ to aromatic or strongly hydrophobic groups. This part appears to accommodate \( R_L \), part of the reason why the selectivity in the dihydroxylation of \( \text{trans-stilbene} \) is so high.

The asymmetric dihydroxylation is much less fussy about the alkenes it will oxidize than Sharpless’ asymmetric epoxidation. Osmium tetroxide itself is a remarkable reagent, since it oxidizes more or less any sort of alkene, electron-rich or electron-poor, and the same is true of the asymmetric dihydroxylation reagent. The following example illustrates both this and a synthetic use for the diol product.

The chemists at Lilly in Spain who made this diol wanted to turn it into the protected amino acid shown after the dotted arrow as part of the synthesis of an anti-HIV compound. The ease with which diols can be made means that there are a number of reliable methods for transforming them into derivatives which undergo the sort of substitution needed. The one used here was to make the diol into a cyclic sulfate using sulfuryl chloride, \( \text{SO}_2\text{Cl}_2 \). Cyclic sulfates behave like epoxides, and this one opens easily with azide at the more reactive position adjacent to the carbonyl group. Hydrolysis of the remaining sulfate ester, hydrogenation of the azide to the amine, and protection with Boc gave the target compound.

An alternative way of achieving the same transformation to the cyclic sulfate is to use thionyl chloride (\( \text{SOCl}_2 \)) to give a sulfite, followed by ruthenium-catalysed oxidation to the sulfate. Diols can even be converted with retention of stereochemistry directly to epoxides. Treatment of a diol with trimethyl orthoacetate and acetyl bromide gives firstly the cyclic orthoester, which opens with bromide to a regioisomeric mixture of the bromoacetates. The regiochemistry is irrelevant because treatment with base hydrolyses the ester and closes both of the resulting bromoalcohols to the same epoxide.
It’s no surprise that when chemists from Bristol Myers Squibb needed the epoxide below, they turned to asymmetric dihydroxylation rather than either of the epoxidation methods we have shown you. Sharpless epoxidation works only with allylic alcohols, and Jacobsen epoxidation performs poorly here, giving only 70–74% ee (mainly because the substrate is not a cis alkene). However, asymmetric dihydroxylation saves the day with 98% ee and around 90% yield, and a variant of the reaction we have just shown you gives the epoxide, also in 90% yield—well worth the extra step.

![Chemical structure](image)

**Ligand-accelerated catalysis**

Asymmetric dihydroxylation is such a good reaction not just because of the careful way in which the ligands have been designed. It is a good reaction for a more fundamental reason: the reaction on which it is based (osmium-catalysed dihydroxylation) works only very poorly in the absence of the amine ligand. The chiral amine ligands don’t just provide a chiral environment, they accelerate the reaction at the same time. This is what we mean by ‘ligand accelerated catalysis’.

In any asymmetric reaction, we want the reagents to combine with one another only in the presence of the asymmetric influence provided by the chiral ligands. If the reaction works anyway, even without the chiral ligands, we have an uphill struggle because the reagents are quite capable of producing racemic product on their own. Racemic ‘background’ reactions are the reason why many of the reactions you are familiar with because they work so well racemically—addition of Grignard reagents to aldehydes, for example—don’t really have good asymmetric versions. In the next section you will meet some more examples of reactions which are significantly accelerated by the presence of a chiral ligand.

**Asymmetric formation of carbon–carbon bonds**

One of the first reactions you met in this book (Chapters 6 and 9) was the addition of an organometallic reagent to an aldehyde or a ketone. If the products of such an addition are chiral they are of course racemic. How might we make such a reaction enantioselective? One way would be to exploit the idea of ligand-accelerated catalysis and use a reaction which really doesn’t work very well in the racemic series.

This is the case when the organometallic reagent is a dialkylzinc. Diethylzinc is commercially available as a solution in toluene or hexane, but it reacts only very slowly with an aldehyde...
if the two are just left to stir together. However, if a chiral amino alcohol is added, the reaction becomes much faster. The amino alcohol forms a zinc alkoxide in the reaction mixture, and the coordination of this anionic chiral ligand to zinc both accelerates the transfer of zinc's alkyl groups to the aldehyde and makes that transfer enantioselective.

With alkyne nucleophiles, this reaction works with just catalytic amounts of zinc because the alkynylzinc forms in the reaction mixture when a weak base is added. It’s a good way of making alkyne-containing alcohols.

Asymmetric conjugate addition

In Chapter 22 we discussed the fact that copper promotes conjugate addition to electron-deficient double bonds. We can again exploit the low reactivity of organozinc compounds with carbonyl compounds, and with alkenes, if we add a catalytic amount of copper and a chiral phosphorus-containing ligand based on the atropisomeric binaphthyl structure you saw in BINAP. The organozinc has to transmetallate to the organocopper in order to react, and the copper always remains bound to the chiral ligand. Conjugate addition can only take place in a chiral environment, and good ees result.

Organocatalysis

It will not have escaped your notice that most of the reactions we have presented in this chapter have made use of metals. Metals have labile coordination sites that can carry chiral ligands at the same time as they allow substrates and reagents to meet together in a chiral environment and then let the products dissociate so that the catalytic cycle can proceed. But in the early years of the 21st century, several chemists around the world realized that it is not always necessary to use a metal to initiate high levels of enantioselectivity in catalytic reactions. Simple chiral and enantiomerically pure organic molecules, many of them amines, can also react reversibly with substrates, providing a chiral environment and simultaneously activating them towards enantioselective attack.

Here is an example, which picks up where we left off: a catalytic enantioselective conjugate addition. As you know from Chapter 11, aldehydes and ketones react with secondary amines to form enamines, via iminium ions. But this unsaturated aldehyde can't form an enamine because the iminium ion that is generated by condensation with the cyclic secondary amine is not a good enough electrophile.
cannot lose a proton. The iminium ion is the end of the line for this condensation: it is very reactive towards attack by water (which would reversibly regenerate starting materials), but also towards attack by other nucleophiles. We have just what we want for good asymmetric catalysis—an intermediate species that is reactive, chiral, and enantiomerically pure.

If this condensation is done in the presence of a weak nucleophile—strong enough to attack the positively charged iminium ion but not strong enough to attack the aldehyde itself—an addition reaction takes place. A pyrrole will do: pyrroles react well with cations. The phenyl ring highlighted in green hangs over the front of the molecule so the pyrrole has no choice but to attack diastereoselectively, from behind. The product is an enamine, which in the acid conditions of the reaction is hydrolysed by the water generated in the initial condensation, revealing the aldehyde in enantiomerically enriched form (93% ee) and regenerating the secondary amine catalyst.

This catalyst and strategy were invented by the Glaswegian chemist David MacMillan at the California Institute of Technology (now at Princeton in New Jersey) and given the name ‘organocatalysis’. Organocatalysis makes use of small organic molecules to achieve catalytic asymmetric transformations, and can be distinguished from the more widespread methods of catalysis which typically use metals. We’ll introduce another type of organocatalysis towards the end of the chapter, but before we move on it’s worth looking at this amine catalyst and the way it works in a little more detail.

The geminal dimethyl group highlighted in orange above is also important to the functioning of the catalyst. Without it, there is clearly a danger that the pyrrole will add directly to the C=N bond of the iminium ion, a reaction that would kill the catalyst because the product is an amine and not an enamine. The methyl groups on both faces of the iminium C=N bond stop this happening. The other thing it ensures is the geometry of the iminium C=N bond. This bond is trans so that the alkene can keep away from the quaternary carbon bearing the two orange groups; the benzyl group with the green phenyl may be bigger in terms of total number of atoms, but there is more space for the alkene on that side because the nearest carbon also carries just an H atom. Why is the geometry of the imine important? Well, if any of it were cis, it would present the other face to the pyrrole and would be likely to give the opposite enantiomer of product.

Catalysts aren’t used in such great quantities as chiral auxiliaries, and so in general their synthesis does not need to be quite so direct. Nonetheless as you can see from the examples here, organocatalysts are still generally used in much greater quantities (10–20 mol%) than some of the best metal catalysts. In this case you should be able to spot that the left-hand
portion of the cyclic amine is a derivative of l-phenylalanine. Condensation of its N-methyl amide with an equivalent of acetone gives the catalyst itself.

Here’s a related catalyst—as with the Rh- and Ru-catalysed reactions, fine tuning of the catalyst is important—being used in the synthesis of an important pharmaceutical compound, a COX-2 inhibitor. This time the nucleophile is an indole reacting characteristically at its 3-position.

Asymmetric aldol reactions

You saw in Chapter 33 that it is possible to use aldol reactions to create two new chiral centres in a single step, and that the relative stereochemistry of the two chiral centres depends in many cases on the geometry of the enolate used to do the aldol reaction. The power of an asymmetric aldol reaction is easy to see: it creates two new chiral centres with control over their absolute stereochemistry, and also constructs a new C–C bond. What is more, the products of aldol reactions are very common features in a huge number of natural products known as polyketides—as you will see in the next chapter, polyketides are made by living things using a series of successive enzyme-controlled aldol reactions.

Chiral auxiliary-controlled aldol reactions: the Evans aldol

An aldol reaction is the addition of an enolate to an electrophile, where the electrophile is an aldehyde or a ketone. You have already seen earlier in this chapter how enolates can be used to make new C–C bonds enantioselectively when we explained how to control enolate alkylation with Evans’ chiral auxiliaries. Evans’ auxiliaries also provide one of the most straightforward ways of carrying out asymmetric aldol reactions, and we will start with an example before explaining how asymmetric aldol reactions can be done using catalytic methods.

This aldol reaction is carried out using a base (triethylamine) and dibutylboron triflate plus benzaldehyde. The aldol product is formed with outstandingly good selectivity and in high yield, and all that remains is to remove the auxiliary with base and isolate the hydroxy-acid as a single diastereoisomer and a single enantiomer.

Aldol reactions using the lithium enolate of the acylated auxiliary shown here fail to give good selectivities, so instead we use the boron enolate. The combination of triethylamine and the boron triflate form the stable boron enolate, which has to be cis because the size of the auxiliary prevents the trans enolate forming. Boron has an empty p orbital, and donation into this orbital from the oxygen of the carbonyl group stabilizes the enolate.
Now the aldehyde is added. If the reaction is to take place, the aldehyde must coordinate to the boron because boron enolates aren’t reactive enough to attack aldehydes unless they are activated by coordination to a Lewis acid. However, the aldehyde can’t simply coordinate to the boron atom of the enolate because then the boron will end up with five bonds, which is impossible for a first-row element. So, if the reaction is to continue, the boron has to let go of the auxiliary’s carbonyl group and coordinate to the aldehyde instead.

At this stage something rather remarkable happens: now that the boron is no longer holding the two oxygen atoms of the enolate close together, repulsion between them (they are both electron-rich atoms) forces the auxiliary part of the enolate to swing round through 180° and end up pointing in the opposite direction. This is highly significant for what happens next because you can see from the last structure in the scheme above that this rotation ends up swinging the isopropyl group of the auxiliary round to the underside of the enolate and therefore forcing the auxiliary to react from the front instead of the back.

The diagrams below continue the story. The aldehyde has to attack the front face of the auxiliary, but it also has to do so through what we termed in Chapter 33 a ‘Zimmerman–Traxler transition state’—a six-membered, chair-like cyclic structure which allows the enolate to attack the aldehyde while simultaneously transferring the metal (here the boron) from the enolate oxygen to the new hydroxyl group.

All the usual advantages and disadvantages of chiral auxiliaries apply here: the products are formed in very high selectivity and can be purified to high ee, but the extra steps required to introduce and remove the auxiliary may compromise the overall yield and efficiency of the reaction. Nonetheless, using this method and many others like it, it has now become possible routinely to make polyketide natural products by successive aldol reactions, mimicking nature’s approach to these compounds. In a spectacular demonstration of the power of synthetic chemistry to outperform natural sources, chemists at the Swiss pharmaceutical company Novartis made 60 g of the anticancer compound discodermolide by a synthetic route, including five aldol reactions. Four of these, shown by black C–C bonds in the structure below, used the aldol or alkylation reactions controlled by Evans’ oxazolidinone chiral auxiliaries. To obtain the same quantity from the natural source, the sponge Discodermia, is impossible: the sponge produces minuscule amounts of discodermolide and can be harvested only by using manned submersible vehicles, at some cost to the marine environment.
A variety of catalytic ways of doing asymmetric aldol reactions have also been invented, but space prevents us discussing all but one. This one we highlight firstly because it illustrates the use of a supremely simple biologically derived compound to catalyse a complex reaction, and secondly because this discovery was part of the revolution in catalytic thinking which launched the field of organocatalysis in the early years of the 21st century.

The catalyst we will use is the amino acid l-proline—no derivatization or protection required. It was actually back in 1971 that it was first noted that l-proline will catalyse asymmetric aldols, but until the year 2000 examples were limited to this one cyclization. Treatment of a triketone with proline leads to selective cyclization onto one of the two enantiotopic carbonyl groups. A molecule of proline must condense with the least hindered ketone, and in this case an enamine (rather than an iminium ion) can form. The chiral enamine can select to react with only one of the two other carbonyl groups, and it turns out that it chooses with rather high selectivity the one coloured green in the scheme below. Cyclization, in the manner of a Robinson annelation, and hydrolysis of the resulting iminium ion follow on, releasing the molecule of l-proline to start another catalytic cycle. The isolated product is the bicyclic ketone, in 93% ee.

This remained an oddity of a reaction until 2000, when chemists at the Scripps Institute in California, and then others around the world, took the simple expedient of adding l-proline to many other aldol reactions, with considerable success. With care, excellent results can be obtained. Here is an example.

You will remember from Chapter 26 that crossed aldol reactions between enolizable partners, like these, usually need one of the reagents to be converted to an enolate equivalent to ensure selective reaction. Here, the acetone is in excess, but the components are just stirred together at room temperature in DMSO! The key to success is that one of the two components must be more able to form a reactive enamine with proline than the other. In the case above, the acetone-derived enamine is favoured because (1) enamine formation is reversible, (2) the acetone is in excess, and (3) the enamine from acetone is less hindered and more reactive than the enamine that would arise from the aldehyde.
In the aldol reaction itself, proline's carboxyl group has a key role to play because it can participate in a hydrogen bond that organizes the six-membered transition state in such a way that only one of the possible enantiomeric products can form. The diagram below shows how. Water generated in the initial condensation hydrolyses the iminium product of the aldol and regenerates the proline catalyst.

Organocatalytic aldol reactions also work well with hydroxylated ketones—the reaction below, for example. In this case, the enamine forms with an E double bond, which means that the hydroxyl group has to be equatorial on the six-membered transition state. You should be able to work out from this that the anti aldol has to form.

Enzymes as catalysts

We pointed out at the beginning of the chapter that all enantiomeric purity must ultimately derive from nature. We have almost come full circle: the reactions we have just been looking at use one of nature's protein building blocks, L-proline, directly as a catalyst. Even more intriguingly, the reaction just above, which forms a ketodiol, is extremely reminiscent of the aldol reactions which nature uses to build carbohydrates, as you will see in the next chapter.

Yet nature does not use single amino acids to catalyse asymmetric reactions, it uses enzymes. Enzymes are vastly more efficient than L-proline and catalyse a much wider range of reactions, but while they are also much more complicated, their reactivity derives ultimately from the amino acids they are made up of.

Life uses enzymes to catalyse asymmetric reactions, so the question is—can chemists? The answer is yes, and there are many enzymes that can be produced in quantities large enough to be used in the catalytic synthesis of enantiomerically pure molecules. This field—known as biocatalysis—melds ideas in chemistry and biology, and we do not have the space here to discuss it in detail. We leave you with just one example: the reduction of a ketone to an alcohol with an enzyme known as a ketoreductase.

The ketoreductase takes hydride from the reducing agent NADPH (which you will meet in the next chapter) and transfers it enantioselectively to the carbonyl group in the active site of
the enzyme. This ketoreductase, isolated from yeast, may never have met this non-biological substrate—benzoyloxyacetone—before, but the reaction works. In fact this sort of reaction works so well that ketoreductases are used to carry out the reduction needed to produce the pharmaceutical intermediate discussed on p. 1116 on a 230 kg scale.

Many other groups of enzymes behave similarly: they have evolved to take part in particular biochemical pathways, but they are sufficiently promiscuous that they will happily accept alternative substrates and provide chemically useful products from them. Enzymes are catalysts, like any other. In the next chapter, we take a more detailed look at those biochemical pathways and discuss the organic chemistry of life.

### Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Primary metabolism

Life runs on chemistry, and the chemical side of biology is fascinating for that reason alone. It is humbling to realize that the same molecules are present in all living things, from the simplest single-cell creatures to ourselves. Nucleic acids contain the genetic information of every organism, and they control the synthesis of proteins. Proteins are partly structural—as in connective tissue—and partly functional—as in enzymes, the catalysts for biological reactions. Sugars and lipids used to be thought of as the poor relations of the other two, storing energy and building membranes, but it is now clear that they also have a vital part to play in recognition and transport.

The chemistry common to all living things is known as primary metabolism and the chart overleaf shows the molecules of primary metabolism and the connections between them, and needs some explanation. It shows a simplified relationship between the key structures (emphasized in large black type). It shows their origins—from CO₂ in the first instance—and picks out some important intermediates. Glucose, pyruvic acid, citric acid, acetyl coenzyme A (acetyl CoA), and ribose are players on the centre stage of metabolism and are built into many
important biological molecules. Use this chart to keep track of the relationships between the molecules of metabolism as you develop a more detailed understanding of them. We start with nucleic acids.

**life begins with nucleic acids**

Nucleic acids store genetic information. They are polymers whose building blocks (monomers) are the nucleotides, themselves made of three parts—a heterocyclic base, a sugar, and a phosphate ester. In the example below, adenine is the base (shown in black), adenosine is the nucleoside (base and sugar), and the nucleotide is the whole molecule (base + sugar + phosphate). This nucleotide is called AMP—adenosine monophosphate. Phosphates are key compounds in nature because they form useful stable linkages between molecules and can also be built up into reactive molecules by simply multiplying the number of phosphate residues. The most important of these nucleotides is also one of the most important molecules in nature—adenosine triphosphate or ATP.
ATP is a highly reactive molecule because phosphates are stable anions and good leaving groups. It can be attacked by hard nucleophiles at a phosphate group (usually the end one) or by soft nucleophiles at the CH₂ group on the sugar. When a new reaction is initiated in nature, very often the first step is a reaction with ATP to make the compound more reactive. This is rather like our use of TsCl to make alcohols more reactive or converting acids to acid chlorides to make them more reactive.

There are five heterocyclic bases in DNA and RNA

Nucleic acids are made up of a selection of five bases, two sugars, and the phosphate group. The bases are monocyclic pyrimidines or bicyclic purines and are all aromatic.

- There are only two purine bases found in nucleic acids: adenine (A), which we have already met, and guanine (G)
- The three pyrimidine bases are simpler: uracil (U), thymine (T), and cytosine (C). Cytosine is found in DNA and RNA, uracil in RNA only, and thymine in DNA only.

The coloured parts of the molecules below emphasize the characteristic features of the bases.

The stimulants in tea and coffee are methylated purines

An important stimulant for many is a fully methylated purine present in tea and coffee—caffeine. Caffeine is a crystalline substance easily extracted from coffee or tea with organic solvents. It is extracted industrially with supercritical CO₂ (or, if you prefer, ‘nature’s effervescence’) to make decaffeinated tea and coffee.

If we, as chemists, were to add those methyl groups we would choose to use a reagent such as methyl iodide, but nature uses a much more complicated molecule. There is a great deal of methylating going on in living things—and the methyl groups are usually added by (S)-adenosyl methionine (or SAM), formed by reaction of methionine with ATP. This is a good reaction because sulfur is a good soft nucleophile, triphosphate is a good leaving group, and substitution at primary carbon is easy.
SAM is a sulfonium salt and could be attacked by nucleophiles at three different carbon atoms. Two are primary centres—good for $S_N2$ reactions—but the third is the methyl group, which is even better. Many nucleophiles attack SAM in this way. In the coffee plant, theobromine (a purine also found in cocoa) is converted into caffeine with a molecule of SAM. The methylation occurs on nitrogen partly because this preserves both the aromatic ring and the amide functionality and also because the enzyme involved brings the two molecules together in the right orientation for $N$-methylation.

At this point we should just point out something that it’s easy to forget: there is only one chemistry. There is no magic in biological chemistry, and nature uses the same chemical principles as we do in the chemical laboratory. All the mechanisms that you have studied so far will help you to draw mechanisms for biological reactions and most reactions that you have met have their counterparts in nature. The difference is that nature is very, very good at chemistry, and we humans are only just learning. We still do much more sophisticated reactions inside our bodies without thinking about them than we can do outside our bodies with all the most powerful ideas available to us in the 21st century.

**Nucleic acids exist in a double helix**

One of the most important discoveries of modern science was the elucidation of the structures of DNA and RNA as the famous double helix by Watson and Crick in 1953. They realized that the basic structure of base–sugar–phosphate was ideal for a three-dimensional coil. The structure of a small part of DNA is shown on the right. Notice that the 2′ (pronounced ‘two prime’) position on the ribose ring is vacant. There is no hydroxyl group there: that is why it is called deoxyribonucleic acid. The nucleotides link the two remaining OH groups on the ribose ring and these are called the 3′- and 5′-positions. This piece of DNA has three nucleotides (adenine, adenine, and thymine) and so would be called –AAT– for short.

Each polymeric strand of DNA coils up into a helix and is bonded to another strand by hydrogen bonds between the bases. Each base pairs up specifically with another base—adenine with thymine (A–T) and guanine with cytosine (G–C)—like this.
There is quite a lot to notice about these structures. Each purine (A or G) is bonded specifically to one pyrimidine (T or C) by two or by three hydrogen bonds. The hydrogen bonds are of two kinds: one links an amine to a carbonyl group (black in the diagram) and one links an amine to an imine (green in the diagram). A purine has to pair with a pyrimidine because only the combination of larger purine and smaller pyrimidine bridges the gap between the nucleic acid coils. Look back at the green and orange parts of the structures on p. 1136 and you will see that only one hydrogen bond pairing pattern can work. In this way, each nucleotide reliably recognizes another and reliably pairs with its partner. The short strand of DNA above (–AAT–) would pair reliably with –TTA–.

HIV and AIDS are treated with modified nucleosides

Modified nucleosides are among the best antiviral compounds. The anti-HIV drug AZT (zidovudine) is a slightly modified DNA nucleoside (3'-azidothymidine). It has an azide at C3' instead of the hydroxyl group in the natural nucleoside. A more radically modified nucleoside 3-TC (lamivudine) is active against AZT-resistant viruses. This drug is based on cytosine with the sugar replaced by a different heterocycle, although it is recognizably similar, especially in the stereochemistry. Acyclovir (Zovirax), the cold sore (herpes) treatment, is a modified guanosine in which only a ghost of the sugar remains. There is no ring at all and no stereochemistry.

Cyclic nucleosides and stereochemistry

DNA is more stable than RNA because its sugars lack the 2' hydroxyl groups. In ribonucleic acids, the fact that the 2'- and 3'-OH groups are on the same side of the ring makes alkaline hydrolysis exceptionally rapid by intramolecular nucleophilic catalysis.
The base removes a proton from the 2′-OH group, which cyclizes on to the phosphate link—possible only if the ring fusion is cis. The next reaction involves breakdown of the penta-covalent phosphorus intermediate to give a cyclic phosphate. One nucleoside is released by this reaction and the second follows when the cyclic phosphate is itself cleaved by base.

Another cyclic phosphate that can be formed from a nucleotide is important as a biological messenger that helps to control such processes as blood clotting and acid secretion in the stomach. It is cyclic AMP (cAMP), formed enzymatically from ATP by nucleophilic displacement of pyrophosphate by the 3′-OH group.

Proteins are made of amino acids

DNA encodes the information needed to make proteins in the form of triplets of bases (codons), for example thymine–adenine–cytosine (TAC) in the diagram below. As RNA is synthesized from DNA, these are turned into complementary codons (in the example below, AUG) by pairing up the bases as shown on p. 1138. This RNA forms the instructions for protein synthesis by the ribosome—perhaps the most elaborate molecular structure in the known universe. Each codon of the RNA chain tells the ribosome to add a specific amino acid to the growing protein. For example, the codon AUG indicates methionine, which we met as a component of SAM. Methionine is a typical amino acid of the kind present in proteins, but is also the starter unit of all proteins.

The next codon of RNA directs the ribosome to add the next amino acid, linked to the previous one in the chain by an amide bond. Amino acids used to make proteins have the same basic structure and stereochemistry, shown in the margin, and differ only in the group R.

The process continues as more amino acids are added in turn to the right-hand end of the growing molecule. A section of the final protein might look like the structure below. The skeleton of the protein zig-zags up and down in the usual way; the amide bonds (shown in black) are rigid because of the amide conjugation and are held in the shape shown.

Note that cAMP has a trans 6,5-fused ring junction.

There is a list of the naturally occurring amino acids in Chapter 23 (p. 554), where we discussed the laboratory synthesis of peptides.

Much of the function of enzymes and other proteins derives from their detailed folded conformation, discussion of which is beyond the scope of this book.
Amino acids combine to form peptides and proteins

In nature, the amino acids are combined to give proteins with hundreds or even thousands of amino acids in each one. Small assemblies of amino acids are known as peptides and the amide bond that links them is called a peptide bond.

An important tripeptide is glutathione, present in the tissues of both animals and plants. Glutathione is the ‘universal thiol’ that removes dangerous oxidizing agents by allowing itself to be oxidized to a disulfide. Glutathione is, however, not quite a typical tripeptide. The left-hand amino acid is normal glutamic acid but it is joined to the next amino acid through its \( \gamma\)-CO₂H group instead of the more normal \( \alpha\)-CO₂H group. The middle amino acid is the vital one for the function—cysteine with a free SH group. The C-terminal acid is glycine.

\[
\text{glutathione} = RSH
\]

\[
\gamma\text{-Glu (glutamic acid joined through its } \gamma\text{-CO₂H group)}
\]

\[
\text{cysteine}
\]

\[
\text{glycine}
\]

Thiols are easily oxidized to disulfides and glutathione sacrifices itself if it meets an oxidizing agent. The oxidized form of glutathione can later be converted back to the thiol by reduction with NADH, which you will meet later in this chapter.

\[
\begin{align*}
\text{2 } \times \text{ glutathione} & \rightarrow \text{ oxidizing agent} & \rightarrow \gamma\text{-Glu} \\
& \quad \text{reducing agent} & \text{glycine}
\end{align*}
\]

Glutathione also detoxifies some of the compounds we described earlier in this book as dangerous carcinogens such as Michael acceptors and 2,4-dinitrohalobenzenes. The thiol acts as a nucleophile, inactivating the electrophiles. Covalently bound to glutathione they are harmless and can be excreted. More glutathione will be synthesized from glutamic acid, cysteine, and glycine to replace that which is lost.

Some short peptides, of around ten amino acids, are hormones. Angiotensin II, for example, is a peptide that causes blood pressure to rise—a very necessary thing in some situations but too much and too often leads to heart attacks and strokes.

Angiotensin-converting enzyme (ACE) is the zinc-dependent enzyme that cleaves two amino acids from the end of angiotensin I to give angiotensin II, and ACE inhibitors are used as treatment for high blood pressure because they inhibit this enzyme. Lisinopril is an example: it is a dipeptide mimic, having two natural amino acids and something else. The ‘something else’ is the left-hand part of the molecule, linked to the dipeptide (Lys–Pro) through an amine and not
by an amide bond. This stops enzymes from hydrolysing the molecule. Lisinopril binds to ACE because it is like a natural dipeptide but it inhibits it because it is not a natural dipeptide. Many people are alive today because of this simple deception practised on an enzyme.

**Structural proteins must be tough and flexible**

In contrast with the functional enzymes, proteins such as collagen are purely structural. Collagen is the tough protein of tendons and connective tissue, and is present in skin, bone, and teeth. It contains large amounts of glycine (every third amino acid is glycine), proline, and hydroxyproline (again about a third of the amino acids are either Pro or Hyp).

Hydroxyproline is a specialized amino acid that appears almost nowhere else and, along with proline, it establishes a very strong triply coiled structure for collagen. The glycine is necessary as there is no room in the triple coil for any larger amino acid. Functionalized amino acids are rare in collagen.

**Hydroxyproline and scurvy**

Hydroxyproline is a very unusual amino acid. It is not incorporated into the growing protein chain when collagen is synthesized—instead the collagen molecule is assembled with Pro where Hyp is need. Once the protein is complete, some of the proline residues are oxidized to hydroxyproline. This oxidation requires vitamin C, and without it collagen cannot be formed. This is why vitamin C deficiency causes scurvy—the symptoms of scurvy suffered by 18th-century sailors (loose teeth, sores, and blisters) were caused by the inability to make collagen.

**Antiobiotics exploit the special chemistry of bacteria**

We have repeatedly emphasized that all life has very similar chemistry. From the biochemical point of view the most important division is that separating prokaryotes from eukaryotes. Prokaryotes, which include bacteria, evolved first and have simple cells with no nucleus. Eukaryotes, which include plants, mammals, and all other multicellular creatures, evolved later and have more complex cells, including nuclei. Even then, much of the biochemistry on both sides of the divide is the same.

When medicinal chemists are looking for ways to attack bacteria, one approach is to interfere with chemistry carried out by prokaryotes but not by us. The most famous of these attacks is aimed at the construction of the cell walls of some bacteria that contain ‘unnatural’ (R)- (or D-) amino acids. Bacterial cell walls are made from glycopeptides of an unusual kind. Polysaccharide chains are cross-linked with short peptides containing (R)-alanine (D-Ala). Before they are linked up, one chain ends with a glycine molecule and the other with D-Ala–D-Ala. In the final step in the cell wall synthesis, the glycine attacks the D-Ala–D-Ala sequence to form a new peptide bond by displacing one D-Ala residue.

---

The reason bacteria have evolved to use these ‘unnatural’ D-amino acids in their cell walls is to protect them against the enzymes in animals and plants, which cannot digest proteins containing D-amino acids.
The antibiotic penicillin works by interfering with this step—although this was not even suspected when penicillin was discovered. Penicillin inhibits the enzyme that catalyses the D-Ala transfer in a very specific way. It first binds specifically to the enzyme (so it must be a mimic of the natural substrate) and it then reacts with the enzyme and inactivates it by blocking a vital OH group at the active site. If we emphasize the peptide nature of penicillin and compare it with D-Ala–D-Ala, the mimicry may become clearer.

Penicillin imitates D-Ala and binds to the active site of the enzyme, encouraging the OH group of a serine residue to attack the reactive strained β-lactam. This same OH group of the same serine residue would normally be the catalyst for the D-Ala–D-Ala cleavage used in the building of the bacterial cell wall. The reaction with penicillin ‘protects’ the serine and irreversibly inhibits the enzyme. The bacterial cell walls cannot be completed, and the bacterial cells literally burst under the pressure of their contents. Penicillin does not kill bacteria whose cell walls are already complete but it does prevent new bacteria being formed.

**Sugars—just energy sources?**

Sugars are the building blocks of carbohydrates. They used to be thought of as essential but rather dull molecules whose function was principally the (admittedly useful) storage of energy. In fact they have much more interesting and varied roles than that. We have already noted that ribose plays an intimate role in DNA and RNA structure and function. Sugars are also often found in intimate association with proteins and are involved in recognition and adhesion processes.

Here are two examples. How does a sperm recognize the egg and penetrate its wall? Recognition of a carbohydrate attached to the membrane of the egg was the first event in all of our lives. And how does a virus get inside a cell? Here again, the recognition process involves specific carbohydrates. One of the ways in which AIDS is being tackled with some success is by a combination of the antiviral drugs we met earlier in this chapter with HIV protease inhibitor drugs, which aim to prevent recognition and penetration of cells by HIV.

**Sugars normally exist in cyclic forms with much stereochemistry**

The most important sugar is glucose. It has a saturated six-membered ring containing oxygen and it is best drawn in a chair conformation with nearly all the substituents equatorial. It can also be drawn as a flat configurational diagram. We have already met one sugar in this chapter, ribose, because it was part of the structure of nucleic acids. This sugar is a five-membered saturated oxygen heterocycle with many OH groups. Indeed, you can define a sugar as an oxygen heterocycle with every carbon atom bearing an oxygen-based functional group—usually OH, but alternatively C=O.
The drawings of glucose and ribose show a number of stereogenic centres, with one centre undefined—an OH group shown with a wavy bond. This is because one centre in both sugars is a hemiacetal and therefore the molecule is in equilibrium with an open-chain hydroxy-aldehyde. For glucose, the open-chain form is this.

When the ring closes again, any of the OH groups could cyclize on to the aldehyde but there is no real competition—the six-membered ring is more stable than any of the alternatives (which could have three-, four-, five-, or seven-membered rings—check for yourself). However, with ribose there is a reasonable alternative.

The most important sugars may exist in an open-chain form, as a five-membered oxygen heterocycle (called a furanose, after the five-membered aromatic compound furan) or a six-membered oxygen heterocycle (called a pyranose, after the six-membered pyran). Glucose prefers the pyranose structure; ribose prefers the furanose structure.

**Sugars can be fixed in one shape by acetal formation**

The simplest way to fix glucose in the pyranose form is to trap it as an acetal. Acid-catalysed condensation with an alcohol, methanol, for example, gives an acetal and, remarkably, the acetal has an axial OR group. Acetal formation is under thermodynamic control (Chapter 11) so the axial compound must be the more stable. This is because of the anomeric effect—so-called because this C atom is called the anomeric position and the acetal diastereoisomers are called anomers. The effect is a bonding interaction between the axial lone pair on the oxygen atom in the ring and the $\sigma^*$ orbital of the OMe group.

The formation of acetals allows a remarkable degree of control over the chemistry of sugars. Apart from the simple glucoside acetal we have just seen, there are three important acetals worth understanding because of the way in which they illustrate stereoelectronic effects—the interplay of stereochemistry and mechanism. If we make an acetal from methyl glucoside and benzaldehyde, we get a single compound as a single stereoisomer.
The new acetal could have been formed between any of the adjacent OH groups in the starting material but it chose the only pair (the black OH groups) which give a six-membered ring. The stereochemistry of glucose is such that the new six-membered ring is trans-fused to the old so that a beautifully stable all-chair bicyclic structure results, with the phenyl group in an equatorial position in the new chair acetal ring. Acetal formation is under thermodynamic control and this product is the most stable possible acetal.

Acetal formation from sugars and acetone shows quite different selectivity. For a start, cyclic acetals of acetone prefer to be five- rather than six-membered rings. In a six-membered ring, one of the acetone's methyl groups would have to be axial, so the five-membered ring is preferred. A 5,5 or 5,6 ring fusion is more stable if it is cis, and so acetone acetals (acetonides) form preferentially from cis 1,2-diols. Glucose has no neighbouring cis hydroxyls in the pyranose form, but in the furanose form it can have two pairs. Formation of an acetal with acetone fixes glucose in the furanose form. This is all summarized in the scheme below.

The open-chain form of glucose is in equilibrium with both the pyranose and the furanose forms through reversible hemiacetal formation using the black and green OH groups, respectively. Normally, the pyranose form is preferred, but the furanose form can form a double acetal with acetone, one acetal having two cis-fused five-membered rings and the other being on the side chain. This double acetal is the product isolated from the reaction.

If we want to fix glucose in the open-chain form, we must make an ‘acetal’ of quite a different kind using a thiol (RSH) instead of an alcohol, an aldehyde, or a ketone. The thiol combines with the aldehyde group of the open-chain form to give a stable dithioacetal. The dithioacetal is evidently more stable than the alternative hemiacetals or monothioacetals that could be formed from the pyranose or furanose forms.

Glycosides in nature

Many alcohols, thiols, and amines occur in nature as glycosides, that is as O-, S-, or N-acetals at the anomeric position of glucose. The purpose of attaching these compounds to glucose is often to improve solubility or transport across membranes—to expel a toxin from the cell, for example. Sometimes glucose is attached in order to stabilize the compound so that glucose appears as nature’s protecting group, rather as a chemist might use a THP group (Chapter 23).

The most important N-glycosides are, of course, the nucleotides, which we have already described in some detail.

You saw an example in Chapter 6 (p. 129) where acetone cyanohydrin is found in the cassava plant as a glucoside.
O-Glycosides occur in immense variety with glucose and other sugars being joined to the OH groups of alcohols and phenols to form acetals. The stereochemistry of these compounds is usually described by the Greek letters \( \alpha \) and \( \beta \). If the OR bond is down, it’s an \( \alpha \)-glycoside; if up, a \( \beta \)-glycoside. An attractive example is the pigment of red roses, which is an interesting aromatic oxygen heterocycle (an anthocyanidin). Two of the phenolic OH groups are present as \( \beta \)-glycosides.

It’s often proposed that there are special benefits to health in eating broccoli and brussels sprouts because of the sulfur-containing antioxidants they contain. These compounds are unstable isothiocyanates. They are not usually present in the plant; damage—by cutting or cooking, for example—induces a glycosidase (an enzyme which hydrolyses glycosides) to releases the sulfur compound from its glucose protection. A simple example is sinigrin. The S-glycosides of the sinigrin group start to hydrolyse in the same way. The sulfur atom is the better leaving group when it leaves as an anion (though worse than oxygen when the hydrolysis occurs in acidic conditions) and the anion is additionally stabilized by conjugation.

The next step is surprising. A rearrangement occurs, rather similar to the Beckmann rearrangement, in which the alkyl group migrates from carbon to nitrogen and an isothiocyanate \( (R-N=C=S) \) is formed. Sinigrin occurs in mustard and horseradish, and it is the release of the allyl isothiocyanate that gives these their ‘hot’ taste. When mustard powder is mixed with water, the hot taste develops over some minutes as sinigrin is hydrolysed to the isothiocyanate.

The S-glycoside in broccoli and brussels sprouts that is proposed to offer protection from cancer is somewhat similar but has one more carbon atom in the chain and contains a sulfoxide group as well. Hydrolysis of the S-glycoside is followed by the same rearrangement, producing a molecule called sulforaphane. Sulforaphane protects against cancer-causing oxidants by inducing the formation of a reductive enzyme.

\( \alpha \)- and \( \beta \)-glycosides

It is easy to remember which is which, as long as you accept that people who devise nomenclature must be maliciously foolish. Just as \( E \) means trans and \( Z \) means cis (each letter has the shape of the wrong isomer), so \( \alpha \) means below and \( \beta \) means above—each word begins with the wrong letter.

The Beckmann rearrangement is described in Chapter 36, p. 958.
Vitamin C is a derivative of glucose
Nature makes some important compounds from simple sugars. Vitamin C—ascorbic acid—is one of these. It certainly looks very like a sugar as it has six carbon atoms, each having an oxygen atom as substituent as well as an oxygen heterocycle. Like glutathione, it protects cells from stray oxidants as well as being involved in primary redox pathways (we mentioned earlier its role in collagen synthesis). Its reduced and oxidized forms are shown below.

Most sugars are embedded in complex carbohydrates
The most familiar of all sugars is sucrose—the mixed acetal formed from glucose and fructose. Sucrose is of course sweet, and is easily metabolized into fats. But if three of the OH groups in sucrose are replaced by chlorine atoms, a compound 600 times as sweet is produced: less of it is needed to get the same sweet taste and the chlorines reduce the rate of metabolism so that much less fat is made. This is the compound sucralose, discovered by chemists at Tate & Lyle and now used to sweeten soft drinks.

Sucrose is a disaccharide—two simple sugars linked by an acetal. In general, saccharides have the same relationship to sugars as peptides and proteins have to amino acids. One of the most abundant compounds in nature is a saccharide: cellulose, the structural material of plants. It is a glucose polymer and is produced in simply enormous quantities (about $10^{15}$ kg per year). Each glucose molecule is joined to the next through an acetal formed by attack of the C4 hydroxyl group of one glucose molecule on the anomeric carbon atom of the next. Here is that basic arrangement.
Notice that the anomeric bonds are all equatorial. This means that the cellulose molecule is linear in general outline. It is made rigid by extra hydrogen bonds between the 3-OH groups and the ring oxygen atoms—like this.

The polymer is also coiled to increase stability still further. All this makes cellulose very difficult to hydrolyse, and humans cannot digest cellulose as we do not have the necessary enzymes. Other mammals have evolved devices such as multiple stomachs (in ruminants, such as cattle) to enable them to degrade cellulose.

**Amino sugars add versatility to saccharides**

Amino sugars are carbohydrates into which nitrogen is incorporated. These molecules allow proteins and sugars to combine and produce structures of remarkable variety and beauty. The most common amino sugars are N-acetyl glucosamine and N-acetyl galactosamine, which differ only in stereochemistry. The hard outer skeletons of insects and crustaceans contain chitin, a polymer very like cellulose but made of acetyl glucosamine instead of glucose itself. It coils up in a similar way and provides the toughness of crab shells and beetle cases.

Cell membranes must not be so impermeable as they need to allow the passage of water and complex molecules. These membranes contain *glycoproteins*—proteins with amino sugar residues attached to asparagine, serine, or threonine in the protein. The attachment is at the anomeric position so that these compounds are O- or N-glycosides of the amino sugars. The structure below shows N-acetyl galactosamine attached to an asparagine residue as an N-glycoside.

**Lipids**

Lipids (fats) are the principal components of cell membranes. Along with cholesterol, also a component of the cell membrane, they have acquired a bad name, but they are nonetheless essential to the function of membranes as selective barriers to the movement of molecules. The most common types of lipids are esters of glycerol. Glycerol is just propane-1,2,3-triol but it has interesting stereochemistry. It is not chiral as it has a plane of symmetry, but the two primary OH groups are enantiotopic. If one of them is modified—by esterification, for
example—the molecule becomes chiral. Natural glycerol 3-phosphate is such an ester and it is optically active.

A typical lipid in foodstuffs is the triester formed from glycerol and oleic acid, which is the most abundant lipid in olive oil. Oleic acid is a mono-unsaturated fatty acid—it has one Z double bond in the middle of the C18 chain. This bond gives the molecule a marked kink in the middle. The compound actually present in olive oil is the triester, also kinked.

Oil and water do not mix

The lipid has, more or less, the conformation shown in the diagram with all the polar ester groups at one end and the hydrocarbon chains bunched together in a non-polar region. Oil and water do not mix, it is said, but triglyceride lipids associate with water in a special way. A drop of oil spreads out on water in a very thin layer. It does so because the ester groups sit inside the water and the hydrocarbon side chains stick out of the water and associate with each other.

When triglycerides are boiled with alkali, the esters are hydrolysed and a mixture of carboxylate salts and glycerol is formed. This is how soap is made—hard soap is the sodium salt and soft soap the potassium salt.

When a soap is suspended in water, the carboxylate groups have a strong affinity for the water and so oily globules or micelles are formed with the hydrocarbon side chain inside. It is these globules that remove greasy dirt from you or your clothes.
Mechanisms in biological chemistry

Nature uses the same chemistry as we do in the laboratory, and to do that chemistry she needs reagents. Chemists are free to use temperatures typically ranging 100 °C either side of 20 °C, any solvents they choose, inert or reactive atmospheres, and so on. Not so nature: all nature’s reagents must work at ambient temperature in the presence of water and in the presence of a reactive gas, oxygen. In this section we will survey some of nature’s solutions to these challenges.

Nature’s NaBH₄ is a nucleotide: NADH or NADPH

You met nucleotides, and their role in the structure of nucleic acids, earlier in this chapter. Nature also uses nucleotides as reagents. Here is the structure of AMP, just to remind you of a structure you met before, side by side with a pyridine-containing nucleotide.

AMP—an adenine nucleotide

\[
\text{AMP} = \begin{array}{c}
\text{adenine} \\
\text{phosphate} \\
\text{ribose}
\end{array}
\]

A nicotinamide nucleotide

\[
\text{nicotinamide} \\
\text{nicotinamide adenine dinucleotide, or NAD (or NAD\textsuperscript{+}—note the positively charged pyridinium). Notice that the link is not at all the same as in the nucleic acids. The latter are joined by one phosphate that links the 3’ and 5’ positions. Here we have a pyrophosphate link between the two 5’ positions.}
\]

These two nucleotides can combine together as a pyrophosphate to give a dinucleotide called nicotinamide adenine dinucleotide, or NAD (or NAD\textsuperscript{+})—note the positively charged pyridinium. Notice that the link is not at all the same as in the nucleic acids. The latter are joined by one phosphate that links the 3’ and 5’ positions. Here we have a pyrophosphate link between the two 5’ positions.

Nicotinamide Adenine Dinucleotide

\[
\text{NAD\textsuperscript{+}} \\
\text{Nicotinamide Adenine Dinucleotide}
\]

the reactive part of NAD\textsuperscript{+} and of NADP

NADP has a phosphate group at the 2’ position. This group does not alter the mechanism of action.
The positively charged pyridinium ring is the part of the molecule which does all the work and from now on we will draw only the reactive part for clarity. NAD⁺ is one of nature’s most important oxidizing agents. Some biochemical pathway reactions use NADP instead, but this differs only in having an extra phosphate group on the adenosine portion so the same part structure will do for both. NAD⁺ and NADP both work by accepting a hydrogen atom and a pair of electrons from another compound. The reduced compounds are called NADH and NADPH.

The reduction of NAD⁺ (and NADP) is reversible, and NADH is itself a reducing agent. We will first look at one of its reactions: a typical reduction of a ketone. The ketone is pyruvic acid and the reduction product is lactic acid—both important metabolites. The reaction is catalysed by an alcohol dehydrogenase.

This is a reaction that would also work in the laboratory with NaBH₄ as the reducing agent, but there is a big difference. The product from the NaBH₄ reaction must be racemic—the starting material, reagent, and solvent are all achiral.

But the product from the enzymatic reaction is optically active. The two faces of pyruvic acid’s carbonyl group are enantiotopic and, by controlling the addition so that it occurs from one face only, the enzyme-catalysed reaction gives a single enantiomer of lactic acid.

**Reductive amination in nature**

One of the best methods for making amines in the laboratory is reductive amination, in which an imine (formed from a carbonyl compound and an amine) is reduced to a saturated amine. Common reducing agents include NaCNBH₄ and hydrogen with a catalyst.
This reaction, of course, produces racemic amines. But nature transforms this simple reaction into an enantioselective and reversible one that is beautiful in its simplicity. The reagents are a pair of substituted pyridines called pyridoxamine and pyridoxal, and the enzyme is an aminotransferase.

The mechanism of the amination starts with the formation of an imine from the black amino group and the green carbonyl. Removal of the now very acidic proton between the protonated pyridine and the conjugated imino-carboxylic acid gives a dihydropyridine, which rearomatizes by protonation next to the carboxylic acid. This step is enantioselective, with the proton being delivered from the enzyme. Finally, hydrolysis of the new imine gives pyridoxal and a single enantiomer of the amino acid.

Nature breaks down glucose to produce energy, and in doing so produces smaller molecules which enter the citric acid cycle and are converted ultimately to carbon dioxide. In the other direction, the six-carbon sugar fructose can be made from two three-carbon fragments. The key reaction in both cases is the step in which the C–C bond linking the two C₃ sugars is formed or broken. The C₃ sugars are glyceraldehyde and dihydroxyacetone, both as their phosphate esters, and the reaction between them is an aldol condensation. The enol of dihydroxyacetone phosphate attacks the electrophilic aldehyde carbonyl group of glyceraldehyde 3-phosphate, catalysed by an enzyme named aldolase. The product is a ketohexose (i.e. a six-carbon sugar with a ketone carbonyl group), fructose-1,6-bisphosphate.
No enolate ion is formed in this aldol reaction. Instead a lysine residue in the aldolase enzyme forms an imine with the keto-triose.

Proton transfers allow this imine to be converted into an enamine, which acts as the nucleophile in the aldol reaction. Stereochemical control (it’s a syn aldol) comes from the way in which the two molecules are held by the enzyme as they combine. The product is the imine, which is hydrolysed to the open-chain form of fructose-1,6-bisphosphate.

Many other reactions in nature use enamines, mostly those formed from lysine. However, a more common enol equivalent is based on thiol esters derived from coenzyme A. Coenzyme A is an adenine nucleotide at one end, linked by a 5′-pyrophosphate to pantothenic acid, a compound that looks rather like a tripeptide, and then to an amino thiol. Here is the structure broken down into its parts.

By now you will realize that most of this molecule is there to allow interaction with the various enzymes that catalyse the reactions of coenzyme A. Coenzyme A is conveniently abbreviated in structures to CoASH, where the SH is the vital thiol functional group, and all the
reactions we will be interested in are those of esters of CoASH. These are thiol esters, as opposed to normal alcohol esters, and the difference is worth a few comments.

Thiol esters are less conjugated than ordinary esters, and ester hydrolysis occurs more rapidly with thiol esters than with ordinary esters because in the rate-determining step (nucleophilic attack on the carbonyl group) there is less conjugation to destroy. The thiolate is also a better leaving group.

Another reaction that goes better with thiol esters than with ordinary esters is enolization. This is an equilibrium reaction and the enol has lost the conjugation present in the ester. Again, a thiol ester has less to lose so is more enolized, and it is the enolization of thiolesters of coenzyme A that we are now going to discuss.

We mentioned the citric acid cycle earlier but we have not so far discussed the chemistry involved. The citric acid cycle allows metabolism to shunt carbon atoms between small molecules, and the key step is the synthesis of citric acid from oxaloacetate and acetyl CoA. The reaction is essentially an aldol reaction between the enol of an acetate ester and an electrophilic ketone, and the enzyme which catalyses the reaction is known as citrate synthase.

The mechanism shows the enol of acetyl CoA attacking the reactive ketone. In nature all these reactions are catalysed by the enzyme. In the C–C bond-forming step, one histidine residue removes the enol proton and another histidine, in its protonated form, is placed to donate a proton to the oxygen atom of the ketone. You should see now why histidine is so useful to enzymes: its imidazole ring means it can act either as an acid or as a base at neutral pH.

Even the hydrolysis of the reactive thiol ester is catalysed by the enzyme and histidine again functions as a proton donor, with the hydrolysis, like the enolization, being enhanced by the thiol ester.

The two enol equivalents that we have met so far are quite general: lysine enamines can be used for any aldehyde or ketone and CoA thiol esters for any ester. Another class of enol equivalent—the enol ester—has just one representative but it is a most important one.

**Phosphoenolpyruvate**

Pyruvic acid is an important metabolite in its own right, as we shall see shortly. It is the simplest α-keto-acid (2-oxopropanoic acid). Having the two carbonyl groups adjacent makes them more reactive: the ketone is more electrophilic and enolizes more readily, and the acid is stronger.

Nature uses the enol phosphate of pyruvic acid (phosphoenolpyruvate or PEP) as an important reagent. We might imagine making this compound by first forming the enol and then esterifying on oxygen by some phosphorylating agent such as ATP.
Now, in fact, this reaction does occur in nature as part of the glycolysis pathway, but it occurs almost entirely in reverse. PEP is used as a way to make ATP from ADP during the oxidation of energy-storing sugars. An enol is a better leaving group than an ordinary alcohol, especially if it can be protonated at carbon. The reverse reaction might look like this.

PEP is also used as an enol in the making of carbon–carbon bonds when the electrophile is a sugar molecule. But if PEP is not made by enolization of pyruvate, how is it made? The answer is by dehydration. The phosphate is already in place when the dehydration occurs, catalysed by the enzyme enolase.

You saw in Chapter 17 how simple OH groups can be lost in dehydration reactions. Either the OH group was protonated by strong acid (this is not an option in living things) or an enol or enolate pushed the OH group out in an E1cB-like mechanism. This must be the case here as the better leaving group (phosphate) is ignored and the worse leaving group (OH) expelled.

The shikimic acid pathway

The shikimic acid pathway is responsible for the biosynthesis of a large number of aromatic compounds, particularly in plants. Most important for many mammals is the fact that plants manufacture the aromatic amino acids Phe (phenylalanine), Tyr (tyrosine), and Trp (tryptophan). These are 'essential' amino acids for humans—we have to have them in our diet as we cannot make them ourselves.

So how do plants make aromatic rings? A clue to the chemistry involved comes from the structure of caffeyl quinic acid, a compound that forms about 13% of the soluble solids from coffee beans. A substantial proportion of instant coffee is caffeyl quinic acid.
This ester has two six-membered rings—one aromatic and one saturated. You might imagine making an aromatic ring by the dehydration (losing three molecules of water) of a cyclohexane triol and the saturated ring in caffeyl quinic acid looks a good candidate. It is now known that both rings (shown in black) come from the same intermediate, shikimic acid.

This key intermediate has given its name to nature’s general route to aromatic compounds and many other related six-membered ring compounds: the shikimic acid pathway. This pathway contains some of the most interesting reactions (from a chemist’s point of view) in biology. It starts with an aldol reaction between phosphoenol pyruvate as the nucleophilic enol component and the C₄ sugar erythrose 4-phosphate as the electrophilic aldehyde.

Hydrolysis of the phosphate releases the aldol product, a C₇ α-keto-acid with one new stereogenic centre, which is in equilibrium with a hemiacetal, just like a sugar. This intermediate has the right number of carbon atoms for shikimic acid and the next stage is a cyclization. If we redraw the uncyclized C₇ α-keto-acid in the right shape for cyclization we can see what is needed. The green arrow shows which bond needs to be formed. This bond could be formed by another aldol reaction, and there is an obvious route to the required enol by elimination of phosphate. However, this would require the removal of a proton (green in the diagram) that is not at all acidic.

The problem can be avoided if the hydroxyl group at C₅ is first oxidized to a ketone (using NAD⁺ as the oxidant). Then the green proton is much more acidic, and the elimination becomes an E1cB reaction, similar to the one in the synthesis of PEP. True, the ketone must be reduced back to the alcohol afterwards but nature can deal with that easily. There are obviously several more steps to get to shikimic acid but all the C–C bonds are in place, the most significant of them being formed by aldol reactions.
You can find more on the shikimic acid pathway in the online chapter 'Mechanisms in biological chemistry'.

Natural products

Organic chemists mean something particular by the phrase ‘natural products’. Of course, all the compounds we have so far discussed are natural and their chemistry is common to most living things. But living things also make chemicals by the processes of secondary metabolism that are found in few, if any, other organisms. The flavouring principles of herbs and fruit, the antibiotics from moulds and the toxic alkaloids in plants are all examples. These compounds are what we mean by ‘natural products’, especially if they are useful to humans.

Natural products often seem to have little value to the organism itself, and are made by the processes of secondary metabolism. They are classified by the way they are made into terpenes and steroids, alkaloids, and polyketides.

Solanaceae alkaloids

The Solanaceae family includes not only deadly nightshade (Atropa belladonna—hence atropine) plants but also potatoes and tomatoes. Parts of these plants also contain toxic alkaloids, for example you should not eat green potatoes because they contain the toxic alkaloid solanine.

Atropine is a racemic compound but the (S)-enantiomer occurs in henbane (Hyoscyamus niger) and was given a different name, hyoscyamine, before the structures were known. In fact, hyoscyamine racemizes very easily just on heating in water or on treatment with weak base. This is probably what happens in the deadly nightshade plant.

Thujone is a terpene that is thought to be the poisonous principle in absinthe—the drink that reduced many artists and writers to idiocy in Paris around 1900. Conine is an alkaloid and the poison in hemlock with which Socrates was executed. Thromboxane is a polyketide involved in blood-clot formation and is a human natural product.

Alkaloids are made by amino acid metabolism

Alkaloids were known in ancient times because they are easy to extract from plants and some of them have powerful and deadly effects. Any plant contains thousands of chemical compounds, but some plants, like the deadly nightshade, can be mashed up and extracted with aqueous acid to give a few compounds soluble in that medium, which precipitate on neutralization. These compounds were seen to be ‘like alkali’ and in 1819 Meissner, the apothecary from Halle, named them ‘alkaloids’. Lucrezia Borgia already knew all about this and put the deadly nightshade extract atropine in her eyes (to make her look beautiful: atropine dilates the pupils) and in the drinks of her political adversaries to avoid any trouble in the future. Now, we would simply say that they are basic because they are amines. Below is a selection with the basic amino groups marked in black. Natural products are often named by a combination of the name of the organism from which they are isolated and a chemical part name. These compounds are all amines so all their names end in ‘-ine’. They appear very diverse in structure but all are made in nature from amino acids.
Pyrrolidine alkaloids are made from the amino acid ornithine

Pyrrolidine is the simple five-membered cyclic amine and pyrrolidine alkaloids such as nicotine contain this ring. All are made in nature from ornithine. Ornithine is an amino acid not usually found in proteins (it’s one carbon atom shorter than lysine) but most organisms use it, often in the excretion of toxic substances. If birds are fed benzoic acid (PhCO₂H) they excrete dibenzoyl ornithine. When dead animals decay, the decarboxylation of ornithine leads to putrescine, the smell of rotten meat.

Biosynthetic pathways are usually worked out by isotopic labelling of potential precursors and in the schemes below the isotopically labelled atom is shown with a coloured blob. Some plants—notably the coca plant—produce the simple pyrrolidine alkaloid hygrine, which we will take as an illustration. If ornithine is made with a ¹⁴C label at its α position and fed to the plant, labelled hygrine is isolated. If each amino group in ornithine is labelled in turn with ¹⁵N, the α amino group is lost but the γ amino group is retained.

Further labelling experiments along these lines showed that the CO₂H group as well as the α amino group was lost from ornithine and that the rest of the molecule makes the pyrrolidine ring. The three-carbon side chain in hygrine comes from acetate, or rather from acetyl CoA, and the N-methyl group comes from (S)-adenosyl methionine (SAM, see p. 1136).

Labelling studies such as these tell us the origin of the atoms in the natural product, and we can now work through the biosynthesis—how the molecule is put together from those precursors. The first step is a pyridoxal-catalysed decarboxylation of ornithine.

Now the terminal amino group is methylated by SAM and the secondary amine cyclizes onto the pyridoxal imine to give an aminal. Decomposition of the aminal the other way round expels pyridoxamine and releases the salt of an electrophilic imine.
The rest of the hygrine structure comes from two molecules of acetyl CoA. We saw earlier in this chapter that the thiol ester is a good electrophile and also enolizes easily. We need both reactivities now in a Claisen ester condensation of acetyl CoA. The new keto-ester is very like the acetoacetates we used in Chapter 25 to make stable enolates and the CoA thiol ester will exist mainly as its enol, stabilized by conjugation.

The cell has a good stock of acetyl CoA and its condensation product, and as soon as the iminium ion above is generated, it is attacked by the acetoacetyl CoA. All that remains to form hygrine is the hydrolysis of the CoA thiol ester and decarboxylation of the keto-acid. This is standard chemistry, but you should ensure that you can draw the mechanisms for these steps.

Tropinone is made from hygrine and it is clear what is needed. The methyl ketone must enolize and it must attack another iminium ion resembling the first but on the other side of the ring. A biological oxidant such as NADP is needed.

**Robinson’s tropinone synthesis**

This complex route to tropinone was imitated as long ago as 1917 in one of the most celebrated reactions of all time, Robinson’s tropinone synthesis. Robinson argued on purely chemical grounds that the sequence of imine salts and enols, which later (as shown in 1970) turned out to be nature’s route, could be produced under ‘natural’ conditions (aqueous solution at pH 7) from a C₄ dialdehyde, MeNH₂, and acetone dicarboxylic acid. It worked and the intermediates must be very similar to those in the biosynthesis.
**Benzyl isoquinoline alkaloids are made from tyrosine**

The benzyl isoquinolines are another family of alkaloids of rather different structure. They all have a benzyl group attached to position 2 of an isoquinoline ring. Usually the alkaloids are oxygenated on the benzene ring and many are found in opium poppies (*Papaver somniferum*). For all these reasons papaverine is an ideal example.

[Diagram of structures]

Labelling shows that these alkaloids come from two molecules of tyrosine. One must lose CO₂ and the other NH₃. We can easily see how to divide the molecule in half, but the details will have to wait a moment.

[Diagram showing labelling and tyrosine]

The question of when the extra OH groups are added was also solved by labelling and it was found that dihydroxyphenyl pyruvate (DHPP) was incorporated into both halves but the dihydroxyphenylalanine (an important metabolite, and also a useful medicine, usually called dopa) was incorporated only into the isoquinoline half.

[Diagram showing DHPP and dihydroxyphenylalanine]

The amino acid and the keto-acid are related by a pyridoxal-mediated transaminase and the hydroxylation must occur right at the start.

[Diagram showing transamination and hydroxylation]

Pyridoxal-mediated decarboxylation of dopa gives dopamine and this reacts with the keto-acid to form an iminium ion perfectly placed for an intramolecular electrophilic aromatic substitution by the electron-rich dihydroxyphenyl ring.
This closes the isoquinoline ring in a Mannich-like process with the phenol replacing the enol in the pyrrolidine alkaloid biosynthesis.

The cyclization product is still an amino acid and it can be decarboxylated by pyridoxal. Now we have something quite like papaverine but it lacks the methyl groups and the aromatic heterocyclic ring, which are introduced by methylation with SAM and oxidation.

**Synthesis of isoquinolines**

As with tropinone, it is possible to make benzyl isoquinoline alkaloids very simply under mild conditions in the laboratory, providing that we use an aldehyde as the carbonyl component. The reaction (sometimes known as the Pictet–Spengler reaction) gives a reduced heterocyclic ring, as does the biosynthesis, but chemical oxidation can be used to give the isoquinoline.

The mechanism is straightforward—the imine is formed and will be protonated at pH 6, ready for the C–C bond formation, which is both a Mannich reaction and an electrophilic aromatic substitution.
Notice that it was not necessary to protect the OH groups—the acetal on the lower ring is not for protection, and this group (methylenedioxy or dioxolane) is present in many benzyl isoquinoline alkaloids. It is formed in nature by oxidation of an MeO group ortho to an OH group on a benzene ring.

Fatty acids and other polyketides are made from acetyl CoA

In the last part of this chapter we will show how nature can take a very simple molecule—acetyl CoA—and build it up into an amazing variety of structures. There are two main pathways from acetyl CoA through malonyl CoA and mevalonic acid and each gives rise to two important series of natural products. Malonyl CoA leads to fatty acids and polyketides while mevalonic acid gives terpenes and steroids. We start with the simplest, the fatty acids. The list below shows just a few of the fatty acids that exist: all are present in a typical diet and you’ll find many referred to on the labels of processed foods.

Fatty acids have some important features which you should note:

- They have straight chains with no branching.
- They have even numbers of carbon atoms.
- They may be saturated with no double bonds in the chain or they may have one or more C=C double bonds in the chain, in which case they are usually cis (Z) alkenes. If there is more than one C=C double bond, they are not conjugated (either with the CO₂H group or with each other)—there is normally one saturated carbon atom between them.

Palmitic acid (C₁₆ saturated) is the most common fatty acid in living things. Oleic acid (C₁₈ mono-unsaturated) is the major fatty acid in olive oil. Arachidonic acid (C₂₀ tetra-unsaturated)
is a rare fatty acid, which is the precursor of the very important biological messengers the prostaglandins, thromboxanes, and leukotrienes.

The prevalence of fatty acids with even numbers of carbon atoms suggests a two-carbon building block, the most obvious being acetate. If labelled acetate is fed to plants, the fatty acids emerge with labels on alternate carbons like this.

\[
\text{biosynthesis} \quad \text{OH} \quad \text{O} \quad \text{OH} \quad \text{O} \\
\text{biosynthesis} \quad \text{OH} \quad \text{O} \quad \text{OH} \quad \text{O}
\]

The green blob might represent deuterium (as a CD₃ group) and the black blob ¹³C. In fact, the reactions are more complex than this suggests as CO₂ is also needed as well as CoA and it turns out that only the first two-carbon unit is put in as acetyl CoA. The remainder are added as malonyl CoA. If labelled malonyl CoA is fed, the starter unit, as it is called, is not labelled.

Malonyl CoA
Malonyl CoA is the thiol ester of CoASH and malonic acid. It is biosynthesized by acylation of acetyl CoA with carbon dioxide.

The first stage in fatty acid biosynthesis is a condensation between acetyl CoA (the starter unit) and malonyl CoA with the loss of CO₂. This reaction could be drawn like this, with CO₂ being lost as the new C–C bond is formed. When chemists use malonates, we like to make the stable enol using both carbonyl groups, condense, and only afterwards release CO₂ (Chapter 25). As you saw on p. 1158, nature does this in making acetoacetyl CoA during alkaloid biosynthesis, but here things work differently.

\[
\text{biosynthesis} \quad \text{OH} \quad \text{O} \quad \text{OH} \quad \text{O} \\
\text{no label} \quad \text{OH} \quad \text{O} \quad \text{OH} \quad \text{O}
\]

The next step is reduction of the ketone group. This NADPH reaction is typically stereo- and chemoselective, although the stereochemistry is rather wasted here as the next step is a dehydration, typical of what is now an aldol product, and occurring by an enzyme-catalysed E1cB mechanism. The elimination is known to be a cis removal of H and OH, and the double bond is exclusively trans (E). Finally in this cycle, the double bond is reduced using another molecule of NADPH to give the saturated side chain.

\[
\text{OH} \quad \text{O} \quad \text{SR} \quad \text{SR} \\
\text{OH} \quad \text{O} \quad \text{SR} \quad \text{SR} \\
\text{SR} \quad \text{OH} \quad \text{O} \quad \text{SR} \quad \text{SR}
\]

Now the whole cycle can start again using this newly made C₄ fatty acid as the starter unit and building a C₆ fatty acid and so on. Each time the cycle turns, two carbon atoms are added to the acyl end of the growing chain.

\[
\text{SR} \quad \text{O} + \text{CO}_2 + 2 \times \text{NADPH} \\
\text{SR} \quad \text{O} + \text{SR} \quad \text{O} + 2 \times \text{NADPH}
\]

What is so important about unsaturated fatty acids?
Mammals can insert a cis alkene into the chain, providing that it is no further away from the carbonyl group than C9. We cannot synthesize linoleic or linolenic acids (see chart on p. 1161) directly as they have alkenes at C12 and C15, so these acids must be present in our diet.
But why are we so keen to have them? They are needed for the synthesis of arachidonic acid, a C₂₀ tetraenoic acid that is the precursor for some very interesting and important compounds. This is the biosynthesis of arachidonic acid.

The final product of this chain of events—arachidonic acid—is one of the eicosanoids, so-called because eicosa is Greek for twenty. The leukotrienes resemble arachidonic acid most closely, the prostaglandins have a closed chain forming a five-membered ring, and the thromboxanes resemble the prostaglandins but have a broken chain. All are C₂₀ compounds with the sites of the alkenes (C₅, C₈, C₁₁, and C₁₄) marked by functionality or some other structural feature.

These compounds, made by oxidation of arachidonic acid, are all unstable and all are involved in transient events such as inflammation, blood clotting, fertilization, and immune responses. They are produced locally and decay quickly, and are implicated in autoimmune diseases like asthma and arthritis.

**Aromatic polyketides**

Other starter units such as 4-hydroxycinnamic acid, made from shikimic acid, can be used to build up aromatic compounds. The addition of three malonyl CoA units gives a linear
tetra-"ketone (hence the same of this class of natural product) that can cyclize to resveratrol, a compound in red grape skins that has been suggested as one of the compounds in red wine that protects against heart disease.

Redrawing this intermediate shows how easily it can cyclize to a six-membered ring. Enol formation allows a very favourable aldol cyclization to give a six-membered ring then dehydration and enolization to make the aromatic ring with hydrolysis of the CoA ester and decarboxylation gives resveratrol.

Terpenes are volatile constituents of plants

Terpenes were originally named after turpentine, the volatile oil from pine trees used in oil painting, whose major constituent is α-pinene. The term was rather vaguely used for all the volatile oily compounds, insoluble in water and usually with resinous smells from plants. Oils distilled from plants, which often contain perfumery or flavouring materials, are called essential oils and these too contain terpenes. Examples include camphor from the camphor tree, which is used to preserve clothes from moths, and humulene from hops, which helps to give beer its flavour.

You will notice that they are all aliphatic compounds with a scattering of double bonds and rings, few functional groups, and an abundance of methyl groups. A better definition (that is, a biosynthetically based definition) arose when it was noticed that all these compounds have 5n carbon atoms. Pinene and camphor are C10 compounds while humulene is C15. It seemed obvious that terpenes were made from a C5 precursor and the favourite candidate was isoprene (2-methylbuta-1,3-diene) as all these structures can be drawn by joining together 2-, 3-, or 4-isoprene skeletons end to end.
In fact, this is not correct. Isoprene is not an intermediate, and the discovery of the true pathway started when acetate was, rather surprisingly, found to be the original precursor for all terpenes. The key intermediate is mevalonic acid, formed from three acetate units and usually isolated as its lactone.

The first step is the Claisen ester condensation of two molecules of acetyl CoA, one acting as an enol and the other as an electrophilic acylating agent to give acetoacetyl CoA. We saw the same reaction in the biosynthesis of the pyrrolidine alkaloids earlier in this chapter.

The third molecule of acetyl CoA also functions as a nucleophilic enol and attacks the keto group of acetoacetyl CoA. This is not a Claisen ester condensation—it is an aldol reaction between the enol of a thiol ester and an electrophilic ketone.

We have drawn the product with stereochemistry even though it is not chiral. This is because one of the two enantiotopic thiol esters is hydrolysed while this intermediate is still bound to the enzyme, so a single enantiomer of the half-acid/half-thiol ester results.

The remaining thiol ester is more electrophilic than the acid and can be reduced by the nucleophilic hydride from NADPH. Just as in LiBH₄ reductions of esters (Chapter 23), the reaction does not stop at the aldehyde level, and two molecules of NADPH are used to make the alcohol. This is mevalonic acid.

Mevalonic acid is indeed the true precursor of the terpenes but it is a C₆ compound and so it must lose a carbon atom to give the C₅ precursor. The spare carbon atom becomes CO₂ by an elimination reaction. First, the primary alcohol is pyrophosphorylated with ATP; then the CO₂H group and the tertiary alcohol are lost in a concerted elimination.
So is isopentenyl pyrophosphate the C₅ intermediate at last? Well, yes and no. There are actually two closely related C₅ intermediates, each of which has a specific and appropriate role in terpene biosynthesis. Isopentenyl pyrophosphate is in equilibrium with dimethylallyl pyrophosphate by a simple allylic proton transfer.

The two C₅ intermediates now react with each other. The dimethylallyl pyrophosphate is the better electrophile because it is allylic, and allylic compounds are good at both S₅1 and S₅2 reactions (Chapter 15). Isopentenyl pyrophosphate is the better nucleophile because it can react through an unhindered primary carbon atom to produce a tertiary cation—we can draw the reaction like this:

Although this idea reveals the thinking behind the reaction, in fact it does not go quite like this. The product is one particular positional and geometrical isomer of an alkene and the cation is not an intermediate. Indeed, the reaction is also stereospecific (discovered again by proton labelling, but we will not give the rather complex details) and this too suggests a concerted process.

As soon as we start to make typical cyclic monoterpenes from geranyl pyrophosphate we run into a snag. We cannot cyclize geranyl pyrophosphate because it has a trans double bond! We could cyclize the cis compound (neryl pyrophosphate), and it used to be thought that this was formed from the trans compound as an intermediate.

It is now known that nature gets round this problem without making neryl pyrophosphate. An allylic rearrangement occurs to move the pyrophosphate group to the tertiary centre. This is an unfavourable rearrangement thermodynamically and probably occurs via the allyl cation and is catalysed by Mg(II). There is no longer any geometry about the alkene. The molecule can now rotate freely about a single bond and cyclization can occur. Even if only a small amount of the rearranged allylic pyrophosphate is present, that can rearrange and more can isomerize.
More interesting compounds come from the cyclization of the first formed cation. The remaining alkene can attack the cation to form what looks at first to be a very unstable compound but which is actually a tertiary carbocation with the pinene skeleton. There are many thousands of terpenes with multiple C₅ units all made from mevalonic acid.

The steroids are another group of compounds derived from mevalonic acid. They include sex hormones such as testosterone and progesterone, and the cholesterol needed to build cell membranes but also implicated in the damage to arteries caused by atherosclerosis.

The elucidation of the ways in which organic chemistry underpins life, along with the use of organic chemistry to construct in the laboratory the molecules used by nature, has been one of the greatest scientific success stories of recent decades. In this chapter we have revealed but a glimpse of the immense complexity of the world of biological organic chemistry; you will find an extended version of this discussion in the three chapters on the web, and a book on biochemistry will fill in more detail. The beautiful molecular structures of nature and the reactions used to make them have provided an example for organic chemists to follow—sometimes at a distance, but always in hot pursuit. The next and final chapter of this book tells a few stories of how such scientific inspiration is the key to the future of chemistry, not only for its own sake, but also for the sake of the millions of people whose lives have been improved or even saved by the ingenuity of chemists.

Science advances through interaction between disciplines

Just as the stonemasons who worked out how to build the great gothic cathedrals of the middle ages transformed architecture, the organic chemists who build molecules on a scale $10^{10}$ times smaller have transformed our expectations of everyday life. When we are ill, we expect there to be a drug to treat us; when we need to mend something, we expect there to be a sealant, glue, or coating to solve our problem. We expect paints, plastics, and clothes of any colour. If an engineer needs a material with certain properties of strength and flexibility, she expects organic chemists to be able to make it. If a biologist needs a molecule to inhibit an enzyme selectively, he expects organic chemists to be able to make it. In the future the same will be true of plastics that conduct electricity or emit light, or drugs tailored to your own individual genetic makeup. The creative art of organic chemistry has transformed our ability to understand and manipulate the world on a molecular scale and above, and it has been able to do this because of the collaboration between those who can make molecules and those who can use them—between chemists, physicists, engineers, and materials scientists.

The most dramatic scientific developments involving organic chemistry at the beginning of the 21st century are new methods in medicine from collaborations between organic chemists and biologists. Progress is slow but secure across a whole range of diseases long thought impregnable to treatment. That media favourite, ‘the cure for cancer’, is already not just ‘a cure’ but hundreds of successful cures for the hundreds of diseases collectively called ‘cancer’. At the turn of the twenty-first century, it was the case that there was some chance of survival for all known types of childhood cancer. The drug Glivec, launched in 2001, now essentially cures 75% of patients with chronic myeloid leukemia. 5-Fluorouracil is a well-established chemotherapy drug that slows down the progression of cancer. But in conjunction with Avastin, which prevents tumours developing their own blood supply, it is much more effective against certain colon cancers. Avastin in conjunction with Taxol (launched in 1992) increases Taxol’s effectiveness against breast cancer. Avastin was launched in 2004, and is expected to be the world’s biggest selling drug by 2014.
5-Fluorouracil could hardly be simpler: it interferes with cell proliferation by modifying natural uracil to incorporate a stubbornly unreactive fluorine. Taxol is a rare metabolite of the Pacific yew tree that can be made at great expense in the laboratory, and for a while was produced by chemical modification of a common precursor that can be harvested. It is now made by fermentation using cultured yew tree cells. Avastin is at the other end of the scale of complexity: it is an antibody against a protein involved in blood vessel growth, and we have represented only its gross structure: a detailed structural diagram would be huge. The antibody was induced in mice, its protein sequence was determined and then modified using the techniques of molecular biology which grew out of organic chemistry in the 1960s and 1970s, and it is produced by expression of the modified gene in bacteria. Which of this is chemistry, which is biology, and which is medicine? There is no point deciding.

Chemistry vs viruses

We are going to spend most of this chapter discussing two medical developments, both battles pitting chemists against viruses: one is partly won, and one has fortunately not yet been fought. Like cancer, viruses are an insidious menace because they subvert the body’s own biochemical machinery to cause harm, but since the middle of the last century, with antibiotics being used to treat bacterial infections, the threat from infectious disease seemed to be in retreat. So when AIDS (acquired immune deficiency syndrome) first came into the news in the 1980s, medics struggled to explain the mysterious deaths from normally harmless diseases after the patient’s immune system had been weakened and eventually destroyed. But the cause was soon identified by biologists as a new virus, HIV (human immunodeficiency virus), and antiviral drugs, notably AZT, were used with some success. These drugs imitate natural nucleosides (AZT imitates deoxythymidine) and inhibit the virus from copying its RNA into DNA inside human cells by inhibiting the reverse transcriptase enzyme.

As is often the problem with antiviral (and anticancer) chemotherapy, the drugs also inhibit the normal function of essential human enzymes and are very toxic. But biologists discovered an alternative point of attack. An enzyme unique to the virus cuts up long proteins into small pieces essential for the formation of new HIV particles. If this enzyme could be inhibited, no new viruses would be formed and neither should the inhibitor interfere with human biochemistry.

Blocking HIV protease inhibitors means mimicking the proteins they slice up, but real peptides are usually poor drugs because humans have their own peptidases which quickly cut up ingested proteins by hydrolysis of the amide link. The solution is to make a drug which looks like the peptide but can’t be hydrolysed because the C–N bond of the peptide has been replaced by a C–C bond (green parts of the structures below).
This stops the drug being hydrolysed, but the drug also has to stop the viral protein being hydrolysed. To get it to do this, medicinal chemists used another trick. Enzymes work by binding the transition state for a reaction, and while of course the chemists couldn’t make a transition state (it is by its nature unstable) they made a molecule with a sufficient resemblance to the tetrahedral intermediate for amide hydrolysis (black parts of molecules above) that the protease is tricked into taking it into its active site, where it blocks the protease’s function.

The knowledge that only one of the two hydroxyl groups of the tetrahedral intermediate was needed was acquired from an X-ray crystal structure showing how the enzyme binds the substrate. Other structural information was also used to design the drugs: for example, HIV protease is a dimeric enzyme and experience with this class of protease suggested correctly that more or less symmetrically placed aromatic or heterocyclic rings would greatly improve binding. Two successful protease inhibitors are shown below, with the active site binding portion in brown and the heterocyclic binding portions in green.

These developments looked so promising that Merck set up a new research station at West Point, Pennsylvania, dedicated to this work. The biochemist in charge, Dr Irving Sigal, was one of the victims of the Lockerbie bombing in 1988 but his work lived on in Crixivan (indinavir). In combination with the antiviral agents AZT and 3TC (Lamivudine), shown with the nucleoside it imitates, indinavir revolutionized the treatment of HIV in the 1990s. Before the use of ‘combination therapy’, as it is known, most of those with HIV were dead within 2 years. Now no-one knows how long they will survive as the combination of the three drugs reduces the amount of virus to undetectably low levels.

The AIDS crisis led to cooperation between the pharmaceutical companies unparalleled since the development of penicillin during the Second World War. Fifteen companies set up an AIDS drug development collaboration programme, with government agencies and universities contributing as well. The battle is not yet won, of course, and the HIV protease inhibitors have now been joined by a new generation of non-nucleoside reverse transcriptase inhibitors, such as the DuPont–Merck compound efavirenz. These commonly join the other drugs of the types mentioned above as part of the drug regimes known as ‘highly active antiretroviral therapy’ or HAART. The mixture of drugs used to combat HIV changes as discoveries are made, but life-saving combination therapy of this sort would not be possible without the sort of collaboration between organic chemists, biochemists, virologists, X-ray crystallographers, and molecular modellers that went into discovering and making indinavir.

After indinavir was found to be effective, the job of the chemists was an exceptionally urgent task. They knew that a kilo of compound was needed to keep each patient alive and well for a year (newer HIV protease inhibitors require much smaller doses). Merck built a dedicated plant for the manufacture of Crixivan at Elkton, Virginia, in 1995. Within a year, production was running at full blast and there are millions of people alive today as a result.
The synthesis of indinavir

Indinavir was a formidable synthetic target. It was probably the most complex compound ever made in quantity by organic synthesis and the 3 g per day dose meant that huge quantities were required. The complexity largely arises from the stereochemistry. As with all chiral new drugs, it is a single enantiomer: there are five stereogenic centres, marked with coloured circles on the diagram below, and their disposition means that three separate pieces of asymmetric synthesis must be devised.

The challenge with indinavir, as with any drug, is to make it efficiently: high yields, few steps. We can start by looking at some likely disconnections, summarized in the scheme above. They are all disconnections of the sorts you met in Chapter 28, and they all correspond to reliable reactions. These disconnections split the molecule into five manageable fragments, three of which contain stereogenic centres and will have to be made as single enantiomers. One of the orange stereogenic centres would have to be made in the enolate alkylation step, so this step will need to be diastereoselective.

Let’s take the three chiral fragments in turn. First, the simplest one: the central epoxide. The reagent we need here will carry a leaving group, such as a tosylate, to allow it to alkylate the piperazine to the left, and it can easily be made from an epoxyalcohol. This gives a very good way of making this compound as a single enantiomer—a Sharpless asymmetric epoxidation of allyl alcohol.

Next, the piperazine fragment. This has two nucleophilic nitrogen atoms and they will both need protecting with different protecting groups to allow them to be revealed one at a time. It will also need to be made as a single enantiomer. In an early route to indinavir, this was done by resolution, but enantioselective hydrogenation provides a better alternative. Starting from a pyrazine derivative, a normal hydrogenation over palladium on charcoal could be stopped at the tetrahydropyrazine stage. The two nitrogens in this compound have different reactivities because one is conjugated with the amide while one is not (the curly arrows in the margin show this). The more nucleophilic nitrogen—the one not conjugated with the amide—was protected with benzyl chloroformate to give the Cbz derivative. Now the less reactive nitrogen can be protected with a Boc group, using DMAP as a base.
You met asymmetric hydrogenation using BINAP complexes of rhodium in Chapter 41 as a method for the synthesis of amino acids. The substrate and catalyst are slightly different here, but the principle is the same: the chiral ligand, BINAP, directs addition of hydrogen across one of the enantiotopic faces of the double bond with almost perfect enantioselectivity and in very high yield. A further hydrogenation step allowed selective removal of the Cbz group, preparing one of the two nitrogen atoms for alkylation.

![Chemical structure]

The remaining chiral fragment is a compound whose synthesis was discussed in Chapter 39. It can be made on a reasonably large scale (600 kg) in one reaction vessel, starting from indene. First, the double bond is epoxidized, not with m-CPBA but with the cheaper hydrogen peroxide in an acetonitrile/methanol mixture, which generates a peroxyimidic acid (the C=N analogue of a peracid) as the active oxidant. Acid-catalysed opening of the epoxide leads to a cation, which takes part in a reversible Ritter reaction with the acetonitrile solvent, leading to a single diastereoisomer of a heterocyclic intermediate, which is hydrolysed to the amino-alcohol.

![Chemical structure]

The product is, of course, racemic but, as it is an amine, resolution with an acid should be straightforward. Crystallization of its tartrate salt, for example, leads to the required single enantiomer in 99.9% ee. With such cheap starting materials, resolution is just about acceptable, even though it wastes half the material. It would be better to oxidize the indene enantioselectively, and the solution here, as you saw in Chapter 41, is to use a Jacobsen epoxidation, which gives the epoxide in 79% yield and 84% ee.

![Chemical structure]

Only one, orange, stereogenic centre remains, and its stereoselective formation turns out to be the most remarkable reaction of the whole synthesis. The centre is the one created in the planned enolate alkylation step, shown in the margin. The obvious way to make this centre is to make Y a chiral auxiliary, which would direct a diastereoselective alkylation before being removed and replaced with the amino-alcohol portion.

But the Merck chemists noticed that amino alcohol itself, certainly once protected, has a remarkable similarity to Evans’ oxazolidinone auxiliaries anyway, and it turns out that this amino alcohol will function very successfully as a chiral auxiliary, which does not need to be removed, avoiding waste and saving steps! The amino alcohol was acylated with the acyl chloride, and the amide was protected as the nitrogen analogue of an acetonide by treating with 2-methoxypropene (the methyl enol ether of acetone) and an acid catalyst. The enolate

Turn to pp. 1066–1067 for details of the mechanisms in this reaction sequence and an explanation for its cis diastereoselectivity.

---

**CHEMISTRY VS VIRUSES**

2069_Book.indb   1173 12/12/2011   8:56:26 PM
of this amide reacts highly diastereoselectively with alkylating agents, including, for example, allyl bromide.

The reason for the stereoselectivity is not altogether clear, but we would expect the bulky nitrogen substituents to favour formation of the cis enolate. With the amino-alcohol portion arranged as shown, the top face is more open to attack by electrophiles. The enolate also reacts diastereoselectively with the epoxy-tosylate prepared earlier. The epoxide, being more electrophilic than the tosylate, is opened first, giving an alkoxide, which closes again to give a new epoxide. The absolute configuration at the stereogenic centre within the epoxide was, of course, already fixed (by the earlier enantioselective Sharpless epoxidation).

Three of the five fragments have now been assembled, and only the two amine alkylations remain. The first alkylation makes use of the epoxide to introduce the required 1,2-amino-alcohol functionality. The protected enantiomerically pure piperazine reacted with the epoxide, and the product was treated with acid to deprotect both the second piperazine nitrogen and the gem-dimethyl group left over from the earlier chiral auxiliary step. The newly liberated secondary amine was alkylated with the reactive electrophile 3-chloromethyl pyridine, and the final product was crystallized as its sulfate salt.

**The synthesis of oseltamivir**

Our second example of the use of chemistry to save lives is more recent. Several times in the last century major epidemics of influenza have caused deaths, sometimes running into millions. Virologists tell us that a global influenza pandemic is a constant danger, and a number of times in recent years highly aggressive forms of the flu virus have found their way from other animals (often poultry or pigs) into the human population. Fortunately, at the time of writing, none has caused more than a few thousand deaths, the most serious being the swine flu pandemic of 2009–10, which claimed the lives of 18,000 people, many of them in Mexico.
To put this in context, the 1918 flu epidemic, which was caused by the same strain (H1N1) of virus, killed 50–100 million, 3% of the world’s population at the time.

Vaccination can prevent the spread of flu, but influenza vaccines are slow to produce and difficult to generalize because of the rate of mutation of the virus. So the first line of defence is a class of antiviral compounds known as neuraminidase inhibitors. Neuraminidase is an enzyme used by the flu virus that targets human cell-surface carbohydrates containing neuraminic acids and allows the virus to release itself from the host cell. Inhibition of this enzyme prevents the new virus particles from spreading.

The drug oseltamivir (Tamiflu), developed by the companies Gilead and Roche, is a neuraminidase inhibitor. Like the HIV proteases described above, it has enough structural similarity with the enzyme’s substrate to bind to the enzyme, but once bound it blocks the enzyme’s activity. No-one knows how much oseltamivir might be needed if ever a flu pandemic took hold, but clearly the safest course of action is to stockpile the compound in readiness for such an event. The first manufacturing route to oseltamivir made use of the natural product (–)-quinic acid as a naturally derived starting material. Quinic acid is found in coffee beans, but is not available in sufficient quantities for widespread use.

A preferable starting material, and the one that for several years now has been used as the source of the commercial drug, is (–)-shikimic acid. Shikimic acid is the plant metabolite that provides the biochemical precursor to the aromatic amino acids such as phenylalanine, tyrosine, and tryptophan. It is abundant in the spice star anise, grown in China, which can yield 3–7% of shikimic acid.

The similarity of both quinic and shikimic acid with the target drug is obvious; what is perhaps remarkable is just how many steps it takes to get from one to the other. The majority of these steps are concerned with the introduction of the two amino substituents with inversion of stereochemistry at the coloured stereogenic centres. Chiral pool syntheses often have to take long convoluted routes to correct relatively minor ‘errors’ of structure and stereochemistry. Here this is simply the price we have to pay for a starting material that has the valuable qualities of enantiomeric purity and the right hydrocarbon skeleton.

Oseltamivir is an ethyl ester, and esterification comes first, followed by selective protection of the cis diol (the cis-6,5-ring system is more stable than the alternative trans) and conversion of the remaining hydroxyl group to a methanesulfonate leaving group.

The dioxolane, which is crystalline and easily purified, is then exchanged for the acetal derived from pentan-3-one, ready for a reduction to the rather challenging hindered ether (direct alkylation with a hindered alkyl halide would struggle to avoid competing E2 elimination).
The reduction of the acetal is catalysed by a Lewis acid and goes via an oxonium ion, which collects hydride from the mild reducing agent triethylsilane. Silanes react only with cationic electrophiles. The oxonium ion could open either way, but this one is less hindered and possibly allows the titanium some favourable interaction with the mesylate substituent.

As often in the synthesis of 1,2-difunctionalized compounds, an epoxide is a key intermediate, and in this case an epoxide forms by closure of the newly revealed hydroxyl group onto the mesylate leaving group in base.

Two amino groups now need introducing with rather specific stereoselectivity, and the next key intermediate is an aziridine, the nitrogen analogue of an epoxide. Azide is not completely regioselective in opening this epoxide, but both regioisomers are formed with complete inversion of configuration.

Azides may be reduced to amines with triphenylphosphine in what is known as the Staudinger reaction. The probable mechanism involves attack of triphenylphosphine on the azide and formation of a phosphinimine via a four-membered intermediate—notice the similarity with the Wittig reaction!

The phosphinimine, in the presence of water, hydrolys to an amine—overall a molecule of nitrogen is lost and a molecule of water is ‘dismembered’ and shared between the reagents.

When the azide has an adjacent hydroxyl group, something more interesting happens: the phosphinimine intermediate in the reaction is intercepted by the alcohol, which turns itself into a leaving group. Extrusion of the stable phosphine oxide gives an aziridine, with inversion of stereochemistry as the nitrogen displaces the leaving group. Here is the result with the major azide from the oseltamivir synthesis:
In this case, it doesn’t matter which azide you start with: triphenylphosphine converts them both to the same aziridine. Like epoxides, aziridines open with nucleophiles under acid catalysis, and azide is used again to put in the second amino group by attack at the less hindered end of the aziridine. To get the right amino group acetylated, the amide is formed before the azide is reduced, this time with tributylphosphine. The drug is formulated as a stable phosphate salt by treatment with phosphoric acid.

This is not, by any stretch of the imagination, an efficient synthesis, not least because there are two uses of potentially explosive azides, and large amounts of waste are produced from the phosphine steps. However, for several years it was the best route available, and Roche operated it as a manufacturing process on a tonne scale. In the last few years, however, several modifications have been published, and among the most efficient of the alternatives was one devised in 2006 by the Nobel prize-winning chemist E. J. Corey. Corey’s route built on the fact that oseltamivir is a cyclohexene, and as you saw in Chapter 34 cyclohexenes are made efficiently by a Diels–Alder reaction.

Corey’s research group combined the two very cheap reagents butadiene and trifluoroethyl acrylate in the first step of their alternative synthesis: the cycloadduct already has the scaffold of oseltamivir. Not starting with a natural product has its advantages and disadvantages: no longer is supply limited by the world production of coffee beans or star anise, and no longer is there a need to make do with a compound of the wrong relative stereochemistry, wasting valuable resources inverting stereogenic centres in the course of the synthesis. However, as you know from Chapter 41, making an enantiomerically pure compound like oseltamivir must involve a natural compound somewhere along the line. Diels–Alder reactions are catalysed by
Lewis acids, and so by using a catalytic amount of the chiral Lewis acid (whose structure is evidently based on that of the CBS catalyst) it was possible to induce the cycloaddition to proceed enantioselectively.

The product of the Diels–Alder reaction has the ester substituent in place, and the stereochemistry at the single chiral centre has to be used to control stereochemistry at new centres in the molecule. We discussed strategies for doing this in Chapters 32 and 33, and in this case the use of a tethered nucleophile (p. 847) allowed the first amino group to be introduced with the correct stereochemistry. Conversion of the ester to an amide followed by treatment with iodine induced in the nitrogen equivalent of an iodolactonization (an iodolactamization), placing the nitrogen syn to the ester and the iodide trans.

The next key intermediate is a diene, which is reached by an overall oxidation of the iodide: protection of nitrogen and elimination of the iodide gives the only possible alkene. Radical bromination with NBS followed by treatment with base in ethanol both hydrolyses the lactam and eliminates bromide to give the diene.

Now for the second nitrogen substituent. Bromination of the less electron deficient end of the diene with N-bromoacetamide in the presence of SnBr4 leads to an intermediate bromonium ion which is opened by the acetamide by-product at the more reactive end adjacent to the alkene, giving a trans diaxial product.

Treatment with base leads to cyclization to an aziridine, and this time the ether is introduced by a copper-catalysed ring opening of the aziridine with 3-pentanol. Treatment with phosphoric acid removes the Boc protecting group and converts the product to oseltamivir phosphate.

Overall, Corey’s route uses just 12 steps, and gives a yield of 30%—about double that of the route from shikimic acid. But much work remains to be done: several of the steps require
conditions or solvents (such as carbon tetrachloride) that are unsuitable for industrial use. Advances are still being made, with even shorter routes being reported since 2006. In some ways it would be best if this vital work were never made necessary, but across the world chemists are working in similar ways to relieve suffering, and potential suffering, caused by illness and disease.

The future of organic chemistry

Not all organic chemists can be involved in such exciting projects as the launching of a life-saving antiviral drug. Some most certainly have to be: resistant bacteria are fast catching up with our current range of antibiotics, and it is teams of organic chemists, in conjunction with biologists, who will be able to erect the next line of defence against these infections. But the chemistry used in such frontline projects is often the product of work by chemists in other institutions who had no idea that it would eventually be used to make a vital drug.

Take the millions of lives saved by the synthesis of indinavir, for example. This drug would not have been possible had not the Sharpless and Jacobsen asymmetric epoxidations, the catalytic asymmetric reduction, and the stereoselective enolate alkylation, along with many of the methods tried but not used in the final synthesis, been invented and developed by organic chemists in academic and industrial research laboratories. Some of the more famous names involved, like Sharpless, Jacobsen, and Noyori, invented new methods, while others modified and optimized those methods, and still others applied the methods to new types of molecules. Yet all built on the work of other chemists.

We can delve deeper into one of the steps in the indinavir synthesis. In 1980 Giovanni Casiraghi, a rather less famous chemist from the University of Parma, published a paper in the Journal of the Chemical Society about selective reactions between phenols and formaldehyde. He and his colleagues made the modest discovery that controlled reactions to give salicylaldehydes could be achieved in toluene with SnCl4 as catalyst. The reaction is regioselective for the ortho isomer and the paper described the rather precise conditions needed to get a good yield.

The reaction was also successful for substituted salicylaldehydes. When Jacobsen came to develop his asymmetric epoxidation, he chose salens as his catalysts, partly because they could be made so easily from salicylaldehydes.

Jacobsen epoxidation turned out to be the best large-scale method for preparing the cis-aminoindanol for the synthesis of indinavir. This process is very much the cornerstone of the whole synthesis. It cannot have entered Casiraghi’s wildest dreams that his work might someday be useful in a matter of life and death. Neither did his four co-workers nor Jacobsen’s more numerous co-workers see clearly the future applications of their work. By its very nature it is impossible to predict the outcome or the applications of research. But one thing is certain: good research and exciting discoveries come from a thorough understanding of the fundamentals of organic chemistry.

When Jacobsen’s epoxidation was fully described in 1998–99, the Casiraghi method was abandoned in favour of an even older method discovered in the 1930s by Duff. The remarkable Duff reaction uses hexamethylenetetramine, the oligomer of formaldehyde and ammonia, to provide the extra carbon atom. The now otherwise unknown Duff worked at Birmingham Technical College. Later in 1972, a William E. Smith, working in the GEC chemical laboratories...
at Schenectady, New York, found how to make the Duff reaction more general and better yielding by using CF₃CO₂H as catalyst. Even so, this method gives a lower yield than the Casiraghi method but it uses less toxic reagents (in particularly it avoids stoichiometric tin) and is more suitable for large-scale work. When Duff was inventing his reaction or Smith was modifying the conditions, asymmetric synthesis was not even a gleam in anyone’s eyes. It is impossible even for the inventor to predict whether a discovery is important or not.

Where is organic chemistry going next? As we write this chapter, advances are being made in reactions which would have seemed outlandish even just ten years ago. Work published in the years since 2005 has shown, for example, that many reactions of cations can be made to form single enantiomers of products even if they take place just in the vicinity of a chiral anion. Reactions such as the one below, from 2008, promise to revolutionize, yet again, some of the ways in which chemists make chiral compounds.

Finding drugs is a difficult job, and the number of new drugs launched each year is dropping as it becomes harder and more expensive to advance beyond existing treatments and as demands for more stringent safety rightly increase. But new drugs are made because... they can be made! What about all those classes of molecules which have never been made, simply because they have never been needed? Among them may well be molecules that will have all the specific attributes we want a potential drug to exhibit. Techniques known as diversity orientated synthesis are now addressing this idea—how to make and study great families of fundamentally different but potentially revolutionary molecules simply and efficiently. It’s too early to tell, but the hope is that these techniques will provide breakthroughs in the fight against disease by finding completely new ways to attack their causes.

Nature is a superb synthetic chemist, and organic chemists have spent the last century exploring efficient ways of building molecular structures more efficiently than nature. Nature builds molecules a certain way because there is no alternative—molecules can be biosynthesized only if the enzymes to make them exist; enzymes are only made from the same 20 amino acids; amino acids are built into proteins by the same ribosome. The ribosome is the most complex and beautiful molecular structure in the known universe, but it can make only proteins. Chemists, with the periodic table, a supply of raw materials, a laboratory, and their ingenuity can make anything. Sometimes chemists use Nature’s enzymes to do a job, or even force them to evolve to do a job better. By cloning useful enzymes in bacteria and forcing them to mutate, high-speed evolution can be induced, and enzymes can be created which do a job better, faster, or at a different temperature from their original ‘wild type’ ancestors.

More often chemists use reactions nature can never use—Rh, Ru, Pd, or phosphine ligands for that matter have never been exploited by any known biological process. What molecules chemists will make next, and how they make them, may determine the well-being of huge numbers of people in the future, but we may well not know it until then.
That future is yours as you continue your studies in organic chemistry beyond the scope of this book, and if you do you will want to read about modern work in more specialized areas. Your university library should have a selection of books on related topics we have only touched on, such as orbitals and chemical reactions, NMR spectroscopy, molecular modelling physical organic chemistry, photochemistry, enzyme mechanisms, biosynthesis, organometallic chemistry, asymmetric synthesis, supramolecular chemistry, and polymer and materials chemistry. This book will equip you with enough fundamental organic chemistry to explore these topics with understanding and enjoyment, and, perhaps, to discover what you want to do for the rest of your life. All of the chemists mentioned in this chapter and throughout the book began their careers as students of chemistry at universities somewhere in the world. You have the good fortune to study chemistry at a time when more is understood about the subject than ever before, when information is easier to retrieve than ever before, and when organic chemistry is more interrelated with other disciplines than ever before.

alkene metathesis 1023–7 see also metathesis
alkenes 28,
alkenes (continued)

- from McMurry reaction of ketones 982–3
- functional group interconversions of 707
- geometry see alkenes geometry
- HOMO and LUMO of in Diels-Alder 886–91
- hydration of 444–5
- regioselectivity of 444–7
- via boranes 446–7
- hydroboration of 446–7
- hydrobromination of 118–19, 433–4
- radical and ionic regiochemistry compared 571
- hydroformylation of using OXO process 1077
- hydrohalogenation of 433–5
- in Alder ene reaction 894–5
- in rings, diastereoselectivity of reactions 835–6, 842, 844–5
- IR spectrum of 70
- isomerization of, acid catalysed 434–5
- by hydrosilylation-dehydropalladation 1081–2
  - for regiocontrol 570
- isomerization of, in acid 254, 264–6
- isomers of 105
- neighbouring group participation by 935
- NMR spectra of 281
- oxidative cleavage of 443–4, 906–7
- photosomerization of 105
- preference for ring position 570
- radical addition of alkyl halides to 992–6
- radical bromination of 971, 973
- radical reaction with HBr 984–5
- rates of bromination 437–8
- reaction with carbenes to form
  - cyclopropanes 1013–18
  - with hydrogen halides 434–5
  - with hydrogen sulfide 434–5
  - with NBS and alcohol or water 441–2
  - with osmium tetroxide to form diols 442–3, 905–6
- regio- and stereoselective synthesis using
  - vinyl silanes 673–4
  - region in 1H NMR 277–81
- retrosynthetic analysis of 707
- Simmons-Smith cyclopropanation of 1017
- stability of E vs Z 679
- stereoselective electrophilic addition to 439
- stereoselective epoxidation of 866–7
- stereoselective formation 677–93 see also
  - alkenes geometry
- stereospecific electrophilic additions to
  - 440–1, 853–4
- stereospecific formation, from E2
  - elimination reactions 853
- substituted, by palladium catalysis 1096
- summary of stabilizing effects on 405
- Wacker oxidation of to form ketones 1096
- alkoxides, as base for enolate formation
  - 454–6, 595
- as leaving groups 199, 202, 204, 728
- as nucleophile in conjugate addition 503, 511
- as nucleophile in nucleophilic aromatic substitution 518

choice of for deprotonation of ester 596
alkoxy, as functional group 29
alkyl bromides 30 see also alkyl halides
- by reaction of primary alcohols with
  - PBr₃, 329
- by reaction of tertiary alcohol with
  - HBr 329
- from hydrogen bromide and alkene 343–4
- reaction with sodium cyanide to form nitrile 716
- synthesis from alcohols 348
alkyl chains, assembly of 339
alkyl chlorides 30 see also alkyl halides
- from alcohols 348
- from hydrogen chloride and alkene 434–5
- in Friedel–Crafts alkylation 492–3
- rates of solvolysis 338
- reaction with saturated nitrogen heterocycles 791
- synthesis from alcohols 348
alkyl cyanides see nitriles
alkyl diazonium salt 521
alkyl group, migration of 940–4
alkyl halides 30 see also alkyl bromides, alkyl chlorides
- α-elimination of 1008–9
- from alcohols 329–30, 336–7, 348
- from hydrogen halide and alkenes 434–5
- radical addition to alkene 992–6
- reaction with enolates 453
- S₄,1 reaction with alcohols to give ethers 338
- S₂,2 reaction with alcohols to give ethers 340–1
- substitution of halogen for hydrogen 991
- tertiary, alkylation of enolates with 595
- reaction with water 334, 336
alkyl iodides see alkyl halides
alkyl nitrile, as source of nitrogen 521
alkyl radicals, conjugate addition of 998–9, 993–4
- from borane-oxygen method 998–9
- alkyl tosylate, as alkylation agent 596
- alkylating agents 225 see also alkyl alkylation
- and electrophile choice (table) 587
- chiral auxiliary-controlled 1109–10, 1112
- diastereoselective, of trans-fused bicyclic enolates 841–2
- double, of 1,3-dicarbonyl compounds 598
- intramolecular 586
- multiple, how to control 586, 589
- multiple, of amines 700–1
- of 1,3-dicarbonyl compounds 595–8
- of a six-membered cyclic enamine, axial attack 830–1
- of acetoacetate dianion, regioselectivity of 601
- of aldehydes 590–5, 613
- summary 594
- via aza-enolates 593–4
- of alkenes 189, 706–7
- of amines 698, 700–1, 704
- of benzene by Friedel–Crafts reaction 477–8

of butenolides, stereochemical control in 834–5
of carboxylic acids 589–90
of chiral enolates 1110
of dienions 601
of enamines 591–3, 650
of enolates 584–613
- as disconnection in heterocycle synthesis 760, 770
- C-alkylation vs O-alkylation 590
- formed by conjugate addition 603–5
- regioselectivity of 590, 592, 595–7, 598–604, 613
- stereoselective, in indinavir synthesis 1172–4
- summary of methods (table) 612
- with α-halo carbonyl compounds 760–1
- of esters 589, 595–8, 613
- of imines 593–4
- of indole nitrogen 778
- of ketones 588–9, 591–7, 600–4, 613
- of Mannich base 621
- of nitroalkanes 586–7
- of pyrazole with dimethyl sulfate 769
- of saturated nitrogen heterocycles 793
- of sulfoxide anion 661
- of symmetrical ketones 588–9, 591–7, 613
- of unsymmetrical ketones, on less
  - substituted side 588, 592, 600–3, 613
- on more substituted side 595–7, 599–600, 602–4, 613
- S₄,1 of cyclopentanone 595
- of silyl enol ethers 595
- stereoselective, of chiral enolate 867–8
- using palladium 1088–91

resonance) 54–69, 269–70, 408–9
coupling in 416–18
integration in 799
interpretation of 62–3
of compounds labelled with 13C 417
proton decoupled spectra 418
regions of spectrum 56
INDEX
INDEX

1197

carbon-14, half-life of and use as radioactive label 1038
isotopic labelling with, for elucidating biosynthetic pathways 1157
carbon acids, pK of 176–7, 237
carbon atoms, chemical synthesis of 745
carbon chains, abbreviations 23
branched 25–7
drawing 22
isomers of 26
names for 23
carbon dioxide, as solvent 480
in primary metabolism 1134–5
reaction with organometallics 190–1
reaction with phenol 481–2
supercritical, as solvent 1136
carbon rings, naming 24
carbon suboxide 878
carbon acids, pK of 154
carbon–oxygen bond strength 198, 451
carbon–carbon bond length 144
carbon-14, half-life of and use as radioactive label 1038
isotopic labelling with, for elucidating biosynthetic pathways 1157
carbon acids, pK of 176–7, 237
carbon atoms, chemical synthesis of 745
carbon chains, abbreviations 23
branched 25–7
drawing 22
isomers of 26
names for 23
carbon dioxide, as solvent 480
in primary metabolism 1134–5
reaction with organometallics 190–1
reaction with phenol 481–2
supercritical, as solvent 1136
carbon rings, naming 24
carbon suboxide 878
carbon acids, pK of 154
carbon–oxygen bond strength 198, 451
carbon–carbon bond length 144

enolization of 451
evidence for tautomerism of 451–2
hydration of, equilibrium constants for 135
acid/base catalysis of 137–8
evidence from IR 135
steric effects on 134
IR spectra to distinguish between 70, 411
lithium enolates of 587–90
lowest energy conformations of 859–60
models for stereoselective reactions of 859–62, 865
most reactive conformer of 860, 861–2
nitration of 464–5
non-enolizable 454, 622
nucleophilic addition to 125–140
pinacol reaction of 981–4
protection as acetics 228
reaction, with alcohols 135–8, 197, 223–8, 247
with amines to form enamines 233–4
with amines to form imines 229–37
with cyanide ion 125
with enolates 614–54
with phosphonium ylids to form cyclopropanes 666–7
with tosyl azide 1006–7
reactivity series towards nucleophiles 529
self-condensation of, how to avoid 585–613
substitution of 14O for 16O 223
substitution of the carbonyl oxygen atom 222–3
thioacetal formation from 662
unsaturated, migration of double bonds by enolization 459
carbonyl dimidazolide (CDI), as electrophile 742
carbonyl ene reaction 895–6
as functional group 31
acyclic, chelation-controlled attack on 862–5
acyclic, diastereoselective reactions of 858–65
addition of bisulphite 138–40
addition of organometallic reagents to 133, 182, 187, 190–4, 216
α-substituted, effect of substituent size on stereoselectivity 864–5
α,β-unsaturated see α,β-unsaturated carbonyl compounds
as nucleophiles 584–613, 614–655
Bouveau–Blanc reduction to alcohol 981
bromination of 461–4
by oxidative cleavage of alkenes 443–4
complete reduction to alkane 493–4
conversion to epoxides with sulfinium ylids 665–7
cyanohydrins from 125
 cyclic, effect of ring strain on reactivity 135
electrophilic but non-enolizable 622
electrophilic but non-enolizable 622
enantiomeric reduction of 1117
electrophilic, with organometallic reagents 132–3
with water (hydrate formation) 134
with sodium borohydride 130–2
 removal of via thioacetals 540
substitution of C=O 222–39
substitution reactions at 197–221
carbonyl oxide, intermediate in ozonolysis 443, 906
carbonylation, by OXO process, palladium catalysed 1084–5
transition metal catalysed 1076–7
carbopalladation, in palladium catalysed coupling 1079, 1082, 1098
carboxybenzyl see Cbz
carboxyl group 31
carboxylic acid derivatives see also individual functional groups: esters, amides, etc. 198
bromination of 461–2
identification by IR 206, 215, 411
interconversion of, summary 215
reactivity of 205–7, 215
use of 13C NMR to distinguish from aldehyde and ketone 408–10
carboxylic acids, 13C NMR chemical shifts of carbonyl 408–9
acylation of 651–2
alkylation of 589–90
as functional group 31
by amide hydrolysis 212–13
decarboxylation of malonate derivatives 596
by ester hydrolysis 209–10
by oxidation of alcohol 195
by ozonolysis of alkenes 443–4, 907
by Wolff rearrangement 1021
chain extension by Arndt–Eistert reaction 1029
conversion to acyl chlorides 214–15, 730
Curtius rearrangement to amines 1022
ene-diols from in acid solution 456
enolates from 455
from alcohols 546
from aldehydes 546
from nitrites 214, 586
from organometallics and carbon dioxide 190–1
IR spectrum of 67–8
 protection of 555–7
reaction with alcohols under acid catalysis 208
reaction with diazomethane 1003–4
reduction to alcohols 531–2
cis and trans dienophiles, Diels–Alder reactions 881–2
 cis chrysanthemic acid, 1H NMR coupling in 815
cis/trans isomerization, of butane 254
cis/trans isomers 306, 311
cis-9,10-octadecenamide 5
cis-alkenes, from alkynes 537
cis-butenedial (maleic dialdehyde), from furan 736
cis-decalin 378–9, 845
 stereoselective reactions of 845–6 substituted, by hydrogenation of Wieland–Miescher ketone 845
cis-enolate, effect on diastereoselectivity of aldol 868–71
cis-fused bicyclic rings, stereoselectivity in 842–6
cis-jasmone 2, 9, 547
cis-stilbene, epoxidation of 431
citalopram 1103
citratal, industrial synthesis 915
citrinate synthase 1153
citrus fruits, smell of 28
CLA see conjugated linoleic acid
Claisen condensation 640–55
avoiding self-condensation during alkylation 589
between ketones and esters 640
compared with aldol reaction 640
in biosynthesis 1165
in heterocycle synthesis 769
in retrosynthetic analysis 717
intramolecular 652–4
mechanism 640
symmetry in 653–4
to form 1,3-dicarbonyl compounds 766–7
Claisen rearrangement 909–12
Claisen synthesis 848–9
clavicipitic acid 1098–9
clavulanic acid, structure of 790
cleavage, of alkenes, by ozonolysis 906–7
Clemmensen reduction 494, 540, 568
‘click’ chemistry 776
clobutilol 716
clopirac, synthesis of 734, 760
cloproamide 617
condensing enzyme 1162
conditions, of reaction, choice of according to mechanism 329–32, 345
configuration 306, 361–2
absolute and relative 313
assignment of (E/Z) 308
assignment of (R/S) 308–9
determination by NMR 796–7
inversion of, in S2, S3 343–4, 351, 352, 380–1
retention of in Baeyer–Villiger oxidation 935
retention of, in neighbouring group participation 932–4, 936–7
conformation 306, 360–81
effect on coupling constants 796–9, 802
energy difference in staggered vs eclipsed 494, 495
envelope, in five-membered rings 834
half-chair (flattened chair) in cyclohexenes 829
names for (in six-membered rings) 370–1, 373
names for (open chain) 365–6
of 1,3,5-triazine 804
of acyclic acetals 804
of acyclic structures 363–6
of bridged bicyclics 839–40
of butane 365–6
of chiral alkenes 865–6
of chiral compunds 859–60
of chiral enolates 867–8
of cyclobutane 369
of cyclohexanes 374–7
of cyclopentane 370
of cyclopropane 369
of esters 804–5
e of ethane 363–4
five-membered rings 370
of fused bicyclics 841, 842
of norbornane 839–40
of pentane 804
of propane 365
of ring structures 366–79
of saturated heterocycles 796–805
of spiroketals 803
of sugars 801–2

coffee, chemical responsible for smell and taste of 659
instant, component of 1154
collagen 1141
collagenes inhibitor 1112–13
Collins’ reagent 194
collisions, between molecules 108
colour, conjugation and 141, 148–9
combination therapy, in treatment of AIDS 1171
combustion, heat of, for alkanes 367–8
for isooctane (petrol) 250
Comins’ reagent 1079
common names 38 see also trivial names
common organic acids, pK, of 172–3
concentration effects, in radical addition 994–5
condensation, aldol see also aldol
condensation 617
condensing enzyme 1162
coenzymes, definition of 44
coal, as source of organic compounds 3
collagen 1141
pollen, as source of organic compounds 3
combustion, heat of, for alkanes 367–8
for isooctane (petrol) 250
Comins’ reagent 1079
common names 38 see also trivial names
common organic acids, pK, of 172–3
concentration effects, in radical addition 994–5
condensation, aldol see also aldol
condensation 617
condensing enzyme 1162
INDEX

conformation (continued)
of sulfur stabilized anions 660
role in diastereoselective reactions 859–65
twist-boat 830
conformational analysis 360–81
conformational preference, in cyclohexene
oxides 837–8
in five-membered rings 834–5
in four-membered rings 833
in six-membered rings 826–32, 837–9
conformer 366
axial and equatorial, energy difference
374–7
in diastereoselective reactions of acyclic
chiral carboxyls 860, 861–2
conine 790, 1156
coniochaetone A and B, structure and
coniine 790, 1156
conformational analysis
continued
conformation ((1,2-addition) 504–7
effect of nucleophile 506–9
effect of reaction conditions 504–5
effect of structure 505–6
conjugate base 167
in Et18 elimination 399
conjugate reduction 603
conjugate substitution 511–14
conjugated carbonyl compounds see α,β-
unsaturated carbonyl compounds
conjugated linoleic acid 5
conjugation 141–62
and delocalization, defined 145
and heteroatom stabilization of
carbocations in S,N 338–9
effect of solvents on 256
effect on barrier to bond rotation 362
effect on IR spectra 411–12
effect on LUMO of 1,2-dicarbonyl 643–4
effect on NMR 412
effect on radical stability 977–9
effect on reactivity of carbonyl group
205–7, 500–3
effects on enol stability 457–9
in alkenes, effect on 1H NMR chemical
shifts 280–1
in allyl cations 336–7
in amides 241–2
in aromatic rings, effect on 1H NMR
278–80
in pyrrole 735
in thioesters and esters compared 1153
stabilization of carbocation by 336–9
stabilization of transition state in SN2
reaction by 341–2
conrotatory 925–6
conservation of charge, in reaction
mechanisms 118
constant, equilibrium, definition of
242–3 see also equilibrium constant
constitutional isomers 306
contraceptive, oral 187, 949
cooking, hydrolysis during 1145–6
coordinatively saturated 1074
coordinatively unsaturated 1074
Cope rearrangement 913–17
copolymerization 997
cooper, in acylation of Grignard reagents and
organolithiums 218
in Sharpless synthesis of 1,2,4-triazoles 775
copper iodide, use as co-catalyst in
Sonogashira coupling reaction
1087–8
cooper(I) salts, for regioselective nucleophilic
addition to allylic compounds 576
in reaction with diazonium salts 522–3
promotion of conjugate addition by 508–9,
603–5
transmetallation with 508–9
coprostanol 379
Corey, Elías James 1177
synthesis of oseltamivir (Tamiflu) by
1177–9
Corey–Bakshi–Shibata catalyst see CBS
catalyst 1114–15
coryne, synthesis of 793
corylone (caramel and roast meat flavour) 9
COT see cyclooctatetraene
cotton, herbicide for 767
coupling constant, α,β in EPR 976
coupling constant, J, in 1H NMR 288
and conformation 796–9, 802
cis and trans, in rings 814–17
cis and trans, alkenes 293–4, 295, 299–300
factors affecting (summary) 294–5, 300–1
typical values of (table) 300–1
coupling, in 1H NMR 285–301
heteronuclear, in NMR 415–16
1J (geminal) 298–300, 817–24
AB pattern 822–3
and ring size 819–20
between diastereotopic protons 820–4
effect of n-contribution 820
in six-membered rings 819
1J and 3J, influence on magnitude of
(1J,3J) in cyclic alkenes 820
1J (vicinal) 295, 300, 822–3
and Karplus relationship 796–8
and ring size 814–17
axial-axial 797–9, 802, 820
axial-equatorial 797–9
effect of dihedral angle on 796–8
in beta-lactams 816
in cis and trans chrysanthemical acid 815
in cyclic acetals 814
in epoxides 815
in five-membered rings 817
in four-membered rings 815
in furans 817
in penicillins 816
in six-membered rings 797–9, 802
in saturated heterocycles 798
in thienamycin 816–17
in three-membered rings 815
orbital effects in 796–8, 800–1
1J (meta, W, or allylic) in aromatic rings
and alkenes 295–6, 301
allylic, in 1H NMR 295–6, 301
in cyclic alkenes 814–15
long-range 295–6, 301
coupling reaction see cross coupling
Buchwald–Hartwig 1092–5
C–C, palladium catalysed 1079–88, 1098–9
C–N, palladium catalysed 1092–5
Heck 1069, 1079–81
of amino acids 747–8
of organometallics and halides 1082–8
palladium catalysed, summary 1088
COX-2 inhibitor, synthesis of 1129
cracking, of dimers and polymers 248–9
Cram, Donald 936
Cram’s rule, for nucleophilic additions to
carbonyls 860
Crick, Francis 1137
Cristian see indinavir
cross metathesis 1025–6
cross-condensation, of esters 643
in aldol reactions 618
cross-coupling reactions, palladium-catalysed
1082–8
reactivity of halides and triflates 1083–4
crossed aldol reactions 639
asymmetric 1131–2
involving formaldehyde 620
crossover experiments 1038–9
crotonaldehyde 616
crotyl bromide 576
 crude oil, as source of organic compounds 3, 6
cubane, 1H and NMR spectra 420
synthesis via Favorovskii rearrangement 952
α-cuparenone, synthesis via intramolecular C–H carbene insertion 1020
cuprates, in conjugate addition 509, 603–5
atom-specific 119, 131
double headed 217
fish hook, in radical reaction mechanisms 972
in reaction mechanisms 120–4
S-shaped for migration 940

summary 907–8
stereochemistry of 907–8
stereoselective epoxidations of 856
stereochemical requirements for formation by S2+ 836–7
cyclohexenes and cyclohexenones, axial attack on 829–32
barrier to inversion 829
by E1 elimination 389
conformational preference in 829
reactions of 830–2, 850–1
stereoselective epoxidations of 856
cyclohexenol, reaction with HBr 433
cyclohexene oxides, conformational preference in 837–8
regioselectivity of ring opening 836–9, 873
stereochemical requirements for formation by S2+ 836–7
cyclohexenes, and cyclohexenones, axial attack on 829–32
barrier to inversion 829
by E1 elimination 389
conformational preference in 829
reactions of 830–2, 850–1
stereoselective epoxidations of 856
stereochemical requirements for formation by S2+ 836–7
cyclooctadiene, electrocyclic ring closure of 928
cyclooctatetraene, as metal ligand 1071
dianion and dication 158–9, 160
heat of hydrogenation 157–8
structure and bond length of 157, 160
cyclooctene, heat of hydrogenation 157–8
cyclopentadiene, [1,5]-sigmatropic hydrogen shifts in 919
bromination of 579–80
dimerization 248–9
HOMO and LUMO of 920–1
hydroboronation of 446
hydrochlorination of 579
in Diels–Alder reactions 880–1, 884, 1108–9
in synthesis of longifolene 650
monooxidation of 432
stable anion from 162
substituted, by fragmentation reaction 920
cyclohexa-1,3-diene, in Diels–Alder reaction 880
cyclohexadienes, isomerization of 543
cyclohexane, 1H and 13C NMR spectra 60–1, 373–4
barrier to ring-flipping 373–4
how to draw 371–4
cyclohexanes, conformation of 368–9, 370–9
coupling constants and dihedral angles in 796
effects of conformation on E2 elimination 396–7
reactions of 379–81, 826–9, 837–9
stereoisomerism in 376–8
cyclohexanol, pK of 173
cyclohexanone, 1H NMR spectrum 293
cyclohexanones, alkylation of 589
cyclohexene oxides, conformational preference in 827
equatorial vs axial attack 827–9, 832
equilibration and conformational preference of 826, 837–9
how to draw 827
cyclohexene, 1H NMR and 13C NMR spectra 277, 280
heat of hydrogenation 157–8
reaction with hydrogen bromide 433
cyclohexene oxides, conformational preference in 837–8
regioselectivity of ring opening 836–9, 873
stereochemical requirements for formation by S2+ 836–7.
cyclopentadienyl anion 162
as intermediate in E1C elimination 401
as ligand, σ or π complex 1071
cyclopentane, conformation of 370
cyclopentanone, enamine formation from 650
from Nazarov cyclization 927
pseudoequatorial vs pseudoequatorial attack of nucleophiles on 834
substituted, from intramolecular C–H carbene insertion 1019
cyclopentenes, diastereoselectivity of electrophilic addition to 835–6
cyclopentenones, diastereoselectivity in 854–6
synthesis from 1,4-dicarbonyl compounds 759
cyclopane 662
[7]-pana, 1H NMR spectrum 278
cyclopropane, conformation of 369
examples of compounds containing 1016
cyclopropanes, [3,3]-sigmatropic opening of 915
as intermediate in Favorovkii rearrangement 951–2
by alkylation of conjugate addition product 607
by intramolecular alkylation 586
by Simmons-Smith reaction 1017
formation from carbenes and alkenes 1013–19
from sulfur ylid and unsaturated carbonyl compound 666–7
palladium-catalysed formation of 1091
cyclopropyl cation, electrocyclic ring opening of 928
cyclization, Nazarov 927
cypermethrin 128
cystine 555
in glutathione 1140
stereochemistry of 1103
cytidine, modified for HIV treatment 1138
cysteine 1136
1H NMR spectrum 285

dicarbonyl compounds
1,4-diazabicyclo[2.2.2]octane
diaxial interactions 374–7
diastereotopicity 820–4
dibutylamine, pKd
Dibenzoyl peroxide, as radical initiator 571, 696, 697
DIBAL (diisobutylaluminium hydride) 26, 39
Diazotization 521
Diazomethane 3, 350
Diazo transfer agent 1007
Diazonium salt 495, 521
Diels–Alder reaction 877–93 see also cycloaddition, [4+2]
and Alder ene reaction, compared 894–5
chiral auxiliary-controlled 1108–9
effect of solvent 888
enantioselective 1108–9, 1112, 1177–8
in retrosynthetic analysis 882
intramolecular 888–9
kinetic and thermodynamic control in 884–5
Lewis acid catalysis of 891
mechanism of 878–9
molecular orbital diagram of 886
of pyrones 739
of thiophene sulfone 739
preference for endo product 884–5, 887–8
regioselectivity in 889–91
reverse electron demand 887
stereochemistry of, in Diels–Alder reactions 882–9, 921
stereospecific synthesis via Suzuki coupling reaction 1086
by oxypalladation 1097
diene-phenol rearrangement 949–50
specific acid catalysis in 1054
which group migrates in 956
dienophiles 880–1
chiral 1108
HOMO and LUMO of 886–91
stereochemistry of 881–2, 884–9
diethyl adipate 245
diethyl azodicarboxylate see DEAD
diethyl carbonate, in Claisen condensations 645
in crossed ester condensation 643
diethyl ether, as nucleophile 117
from acid-catalysed reaction of ethanol 121–2
stability in the presence of organolithiums 795
use of ‘ether’ as trivial name for 37
diethyl fumarate, conjugate addition to 606
diethyl malonate see malonates
diethyl oxalate, in Claisen condensations 645
in crossed ester condensations 643
in Reissert indole synthesis 779
diethyl tartrate (DET), in asymmetric epoxidation 1120–2
diethylaluminium chloride, as Lewis acid for asymmetric Diels–Alder 1108
diethylamine, pKd of 792
diethylzinc, asymmetric addition to an aldehyde 1126–7
difluoroacetic acid, pKa of 176
difunctional compounds, 1,2-, retrosynthetic analysis of 720
dig nomenclature, in Baldwin’s rules 810
dihedral angle 364, 796
effect on coupling constants in 'H NMR 796–8
dihydrofolic acid synthase 754
dihydrofolic acid 753
dihydropterato synthase 753
dihydropyran, for protection of alcohols 469
dihydropyridines, as heart drugs 764–5
from Hantzsch synthesis 763–4
oxidation of 763, 764
dihydroxyacetone (DHA), as chiral ligand 1123–6
dihydroxyacetone phosphate (DHAP) 1159
dihydroxyacetone phosphate (DHAP) 1159
dihydroxypropionyl (DHP) 1159
from diborane diisobutylaluminium hydride see DIBAL
diisopropylamine, for synthesis of LDA 588

INDEX 1203
elimination (continued)
for enone or enal formation 616
from aldol product 616
from Mannich product 621
in mechanism of Fmoc deprotection 559
in nature 1154, 1156, 1162
leaving groups in 400
of β-halocarbonyl compounds 400–1
rate determining step and rate equation

regio and stereoselectivity 402, 569
stabilization of intermediate 401
to form E-alkenes 684
E2 382–3, 386
anti-periplanar transition state of 395–7
effects of base on regioselectivity of 398–9
effects of steric hindrance 395
evidence for reaction mechanism 396–7
examples of substrates 388
for making alkynes 398
from cyclohexanes, effects of
conformation 396–7
in diene formation 387
of alkyl halides 383, 385–7
of vinyl halides to give alkynes 398
rate equation for 383, 386
regioselectivity of 398–9
stereoelectronic effects in 801–2
stereospecificity of 395–6, 853
with basic nucleophile 382–3
‘Hofmann’s rule’ 399
Peterson 671
radical 974
reductive see reductive elimination
‘Saytsev’s rule’ 399
step in acetal formation 225
elimination reactions, comparison of E1, E2,
and E1Cβ 402
effects of concentration 386
effects of nucleophile 384–5
effects of steric hindrance 385–7
effects of temperature 385–6
entropic effects 385–6
in bicyclic structures 389–90
leaving groups in 390
stereoselective 678, 684–93
vs substitution reactions 384–6, 404–5
elimination-addition mechanism, in benzene
reactions 523–4
enals 500 see α,β-unsaturated aldehydes
enamines 233–4
[3,3]-sigmatropic rearrangement of 916
1H NMR spectrum 280–1
acylation of with acyl chlorides 650
addition to carbonyl compounds 591–3
alkylating agents for 591–3, 650
as specific enol equivalents 608, 624, 632
axial attack on 830–1
formation 233, 591, 791
thermodynamic control over 592
from lysine, enolate equivalent in nature
1151–3
nucleophilicity compared to enolates 591
stability 233
autotomic forms 456–7
enantiomeric excess, measurement of 1110–12
enantiomerically enriched 1110
enantiomerically pure 308
enantiomers 303, 309, 313, 315, 852
and diastereoisomers, distinction between
313–16
difference between 5, 309
in nature 322, 1104–6
separation of 322–7
enantioselective see also asymmetric
enantioselective synthesis 1102–33
enantiotopic 821
faces, definition and examples of 856
endocyclic acids 250–3, 320–3
endo face, in bridged bicyclic compounds 840
endo nomenclature, in Baldwin’s rules 810
endo selectivity, in Diels–Alder reaction
884–5, 887–8, 1108–9
ene reaction 894–6 see also Alder ene reaction
eneediolate, from acyloin reaction of esters

meta-substitution, regioselective formation of 525
metathesis 1023–7, 1099–100
catalysts for 1023
cross 1025–6
e-ne 1026–7
mechanism of 1024
ring-closing 1023–4
methadone, synthesis via pinacol rearrangement 947
methane, bonding and molecular orbitals 98–100
pKₐ of 170
shape of 81
methanesulfonate, as leaving group 349, 390–1
methanesulfonate esters, E1cB step in mechanism of formation 403–4
in eliminations 391, 400
synthesis from alcohols 349
methanesulfonyl acid, pKₐ of 173
methanesulfonyl chloride, elimination to sulfene 404
in synthesis of allylic chlorides 577
methanol, as solvent for S₈,1 reactions 346–7
methine group, in 1H NMR 274–6
methionine 16, 23, 555, 1136, 1139
crystal structure of 44
methoxide, as base in Claissen condensation 647
as nucleophile in conjugate addition 502
N-methoxy-N-methyl amide (Weinreb amide) 219
methoxymethyl cation, in SN1 reactions 338
methyl acetoacetate, 1H NMR spectrum 276
methyl benzenesulfonate, 1H NMR spectrum 488
methyl benzoate, 1H NMR spectrum 488
methylation, shape of 103
methyl chloroformate see chloroformates
methyl cyanoacrylate see superglue
methyl esters, from diazomethane with carboxylic acid 1003–4 see also esters
methyl ethers, as protecting groups 552
methyl group, in 1H NMR 272–6
methyl lactate, 1H NMR spectrum 275
methyl methacrylate, 13C NMR spectrum 409
methyl mycamaminoside, synthesis of 872–3, 1107
N-methyl-N-nitrosotoluensulfonamide, as source of diazomethane 1004
N-methyl-N-nitrosoureia, as source of diazomethane 1004
methyl phenyl sulfide 660
methyl phenyl sulfoxide 660
methyl phenyl sulfone 660
methyl propionate (methyl propynoate), IR spectrum of 390–1
methyl radical, EPR and absorption spectrum of 976
methyl vinyl ketone, conjugate addition to 606
N-methylaniline, IR spectrum of 66
methylation 467 see also alkylation
in biological chemistry 1136–7
of amines by reductive amination with formaldehyde 234–5
of indole nitrogen 778
methylene group, diastereotopicity in 820–4
in 1H NMR 288
methylene insertion reactions, by diazaaldanes 953
methylene synthesis of carbonyl compounds by the Wittig reaction 237–8
methylolithium, 13C NMR spectrum 152
addition to α,β-unsaturated esters 582
N-methylmorpholine-N-oxide see NMO
2-methylxirane see propylene oxide
2-methylpropan-1-ol see isobutanol
2-methylpropan-2-ol see tert-butanol
methyltritylphosphonium bromide, 1H NMR spectrum 416–17
metamid 178–9
metromidazole, synthesis of 743
mevalonic acid 1161, 1165–7
mevalonolactone 1165
MHz, conversion to ppm, in NMR 288
mellisine 1148–9
Michael acceptors 623 see also α,β-unsaturated carbonyl compounds
examples of 500, 605, 609–10
reaction with nitronates 623
unsaturated amides as 610
unsaturated nitriles as 610
nitration, conditions for (continued)
regioselectivity of 486–7
trapping of intermediates 1060–1
nitrenes, formation and rearrangement 1022
nitric acid, for oxidative cleavage of camphor 841
in oxidation of dihydroxybenzidine 783
nitric oxide (NO) 95–6
2] cycloaddition of 773–4,
+ nitric oxide (NO) 95–6
nitro compounds 30, 901
nitro aldol reaction (Henry reaction) 622–4
nitrobenzenes 487–9
in Skraup quinoline synthesis 782
nitration of 487–9
1N, isotopic labelling with, for elucidating biosynthetic pathways 1157
nitrogen, N$_2$, energy level diagram of 86
in oxidation of dihydroxybenzidine 783
substitution on 518
nitrogen acids and bases 174
compared with oxygen bases 177
nitrogen fixing bacteria 188
nitrogen-containing compounds, in mass spectrometry 520–3
comparing with oxygen containing compounds 518
and relation to reactivity 280, 281
summary (table) 276
compared with 13C 269–70
conformation of saturated rings by
796–800, 802
coupling 285–301 see also coupling

WHAT LECTURERS HAVE SAID ABOUT THE FIRST EDITION:

'A magnificent resource.' Angewandte Chemie

'Refreshing, exciting, and motivational.' Tony Barrett, Imperial College London

'This is a book we have all been waiting for! It is based on sound mechanistic reasoning and contains thousands of useful examples for teaching.'

Adam Nelson, University of Leeds

'Represents a milestone in the field of organic chemistry textbooks.'

Times Higher Education

Inspiring and motivating its readers from the moment it was published, Organic Chemistry has established itself in just one edition as the students' choice of organic chemistry text. At heart, the second edition remains true to the first, being built on three principles:

An explanatory approach, through which you are motivated to understand the subject and not just learn the facts;

A mechanistic approach, giving you the skills to explain the chemistry of compounds and to predict the success of reactions you may not have met before;

An evidence-based approach, setting out clearly how spectroscopic and other physical methods tell us the facts of organic chemistry, giving critical depth and context to your understanding.

New to this edition:

► All chapters have been revised and refined to provide a more student-friendly, more logical, and more coherent presentation of the subject.

► Chapters are extensively cross-linked to a bank of over 500 interactive online resources, which help you visualize molecular structure, and gain a deeper and richer understanding of reaction mechanisms.

► Early chapters have been recast to give a more carefully graded learning curve, which builds up chemical ideas step by step and avoids confronting you with too much, too soon.

► Coverage of those topics with particular practical relevance that have developed in the last ten years has been enhanced, including the presentation of metathesis, modern methods of asymmetric synthesis (including organocatalysis), 'click chemistry,' and palladium-catalysed couplings.

► A new chapter on regioselectivity has been introduced, providing (along with the chapter on chemoselectivity) a pause for thought and 'revision session' in the middle of the book.

► Suggestions for further reading have been added to all chapters to help you take the next step in your learning.

A solutions manual to accompany the book, written by Jonathan Clayden, is also available.

Suggested solutions for Chapter 2

PROBLEM 1

Draw good diagrams of saturated hydrocarbons with seven carbon atoms having (a) linear, (b) branched, and (c) cyclic structures. Draw molecules based on each framework having both ketone and carboxylic acid functional groups in the same molecule.

Purpose of the problem

To get you drawing simple structures realistically and to steer you away from rules and names towards more creative and helpful ways of representing molecules.

Suggested solution

There is only one linear hydrocarbon but there are many branched and cyclic options. We offer some possibilities, but you may have thought of others.

- **linear saturated hydrocarbon (n-heptane)**

- **some branched hydrocarbons**

- **some cyclic hydrocarbons**

We give you a few examples of keto-carboxylic acids based on these structures. A ketone has to have a carbonyl group not at the end of a chain; a carboxylic acid functional group by contrast has to be at the end of a chain. You will notice that no carboxylic acid based on the first three cyclic structures is possible without adding another carbon atom.
LINEAR MOLECULES CONTAINING KETONE AND CARBOXYLIC ACID

SOME BRANCHED KETO-ACIDS

SOME CYCLIC KETO-ACIDS

PROBLEM 2

Draw for yourself the structures of amoxicillin and Tamiflu shown on page 10 of the textbook. Identify on your diagrams the functional groups present in each molecule and the ring sizes. Study the carbon framework: is there a single carbon chain or more than one? Are they linear, branched, or cyclic?

Purpose of the problem

To persuade you that functional groups are easy to identify even in complicated structures: an ester is an ester no matter what company it keeps and it can be helpful to look at the nature of the carbon framework too.

Suggested solution

The functional groups shouldn’t have given you any problem except perhaps for the sulfide (or thioether) and the phenol (or alcohol). You should have seen that both molecules have an amide as well as an amine.
The ring sizes are easy and we hope you noticed that one bond between the four- and the five-membered ring in the penicillin is shared by both rings.

The carbon chains are quite varied in length and style and are broken up by N, O, and S atoms.
PROBLEM 3
Identify the functional groups in these two molecules

the heart drug candosatril
a derivative of the sugar ribose

Purpose of the problem
Identifying functional groups is not just a sterile exercise in classification: spotting the difference between an ester, an ether, an acetal and a hemiacetal is the first stage in understanding their chemistry.

Suggested solution
The functional groups are marked on the structures below. Particularly important is to identify an acetal and a hemiacetal, in which both ‘ether-like’ oxygens are bonded to a single carbon, as a single functional group.
PROBLEM 4
What is wrong with these structures? Suggest better ways to represent these molecules.

Purpose of the problem
To shock you with two dreadful structures and to try to convince you that well-drawn realistic structures are more attractive to the eye as well as easier to understand and quicker to draw.

Suggested solution
The bond angles are grotesque with square planar saturated carbon atoms, bent alkynes with 120° bonds, linear alkenes with bonds at 90° or 180°, bonds coming off a benzene ring at the wrong angles and so on. If properly drawn, the left-hand structure will be clearer without the hydrogen atoms. Here are better structures for each compound but you can think of many other possibilities.

PROBLEM 5
Draw structures for the compounds named systematically here. In each case suggest alternative names that might convey the structure more clearly if you were speaking to someone rather than writing.
(a) 1,4-di-(1,1-dimethylethyl)benzene
(b) 1-(prop-2-enyloxy)prop-2-ene
(c) cyclohexa-1,3,5-triene

Purpose of the problem
To help you appreciate the limitations of systematic names, the usefulness of part structures and, in the case of (c), to amuse.
Suggested solution

(a) A more helpful name would be *para*-di-*t*-butyl benzene. It is sold as 1,4-di-*t*-butyl benzene, an equally helpful name. There are two separate numerical relationships.

(b) This name conveys neither the simple symmetrical structure nor the fact that it contains two allyl groups. Most chemists would call it 'diallyl ether' though it is sold as 'allyl ether'.

(c) This is of course simply benzene!

PROBLEM 6

Translate these very poor structural descriptions into something more realistic. Try to get the angles about right and, whatever you do, don’t include any square planar carbon atoms or any other bond angles of 90°.

(a) C₆H₅CH(OH)(CH₂)₄CO₂C₂H₅
(b) O(CH₂CH₂)₂O
(c) (CH₃O)₂CH=CHCH(OCH₃)₂

Purpose of the problem

An exercise in interpretation and composition. This sort of ‘structure’ is sometimes used in printed text. It gives no clue to the shape of the molecule.

Suggested solution

You probably need a few ‘trial and error’ drawings first but simply drawing out the carbon chain gives you a good start. The first is straightforward—the (OH) group is a substituent joined to the chain and not part of it. The second compound must be cyclic—it is the ether solvent commonly known as dioxane. The third gives no hint as to the shape of the alkene and we have chosen *trans*. It also has two ways of representing a methyl group. Either is fine, but it is better not to mix the two in one structure.
PROBLEM 7

Identify the oxidation level of all the carbon atoms of the compounds in problem 6.

Purpose of the problem

This important exercise is one you will get used to very quickly and, before long, do without thinking. If you do it will save you from many trivial errors. Remember that the oxidation state of all the carbon atoms is +4 or C(IV). The oxidation level of a carbon atom tells you to which oxygen-based functional group it can be converted without oxidation or reduction.

Suggested solution

Just count the number of bonds between the carbon atom and heteroatoms (atoms which are not H or C). If none, the atom is at the hydrocarbon level (□), if one, the alcohol level (○), if two the aldehyde or ketone level, if three the carboxylic acid level (●) and, if four, the carbon dioxide level.

Why alkenes have the alcohol oxidation level is explained on page 33 of the textbook.
PROBLEM 8
Draw full structures for these compounds, displaying the hydrocarbon framework clearly and showing all the bonds in the functional groups. Name the functional groups.
(a) $\text{AcO(CH}_2\text{)}_3\text{NO}_2$
(b) $\text{MeO}_2\text{CCH}_2\text{OCOEt}$
(c) $\text{CH}_2=\text{CHCONH(CH}_2\text{)}_2\text{CN}$

Purpose of the problem
This problem extends the purpose of problem 6 as more thought is needed and you need to check your knowledge of the ‘organic elements’ such as Ac.

Suggested solution
For once the solution can be simply stated as no variation is possible. In the first structure ‘AcO’ represents an acetate ester and that the nitro group can have only four bonds (not five) to N. The second has two ester groups on the central carbon, but one is joined to it by a C–O and the other by a C–C bond. The last is straightforward.

![Structures](AcO(CH2)3NO2, MeO2CCH2OCOEt, CH2=CHCONH(CH2)2CN)

PROBLEM 9
Draw structures for the following molecules, and then show them again using at least one ‘organic element’ symbol in each.
(a) ethyl acetate
(b) chloromethyl methyl ether
(c) pentanenitrile
(d) $N$-acetyl $p$-aminophenol
(e) 2,4,6-tri-(1,1-dimethylethyl)phenylamine

Purpose of the problem
Compound names mean nothing unless you can visualize their structures. More practice using ‘organic elements’.
Suggested solution

The structures are shown below—things to look out for are the difference between acetyl and acetate, the fact that the carbon atom of the nitrile group is included in the name, and the way that a \textit{tert}-butyl group can be named as ‘1,1-dimethylethyl’.

![Structures](image)

PROBLEM 10

Suggest at least six different structures that would fit the formula $\text{C}_4\text{H}_7\text{NO}$. Make good realistic diagrams of each one and say which functional groups are present.

Purpose of the problem

The identification and naming of functional groups is more important than the naming of compounds, because the names of functional groups tell you about their chemistry. This was your chance to experiment with different groups and different carbon skeletons and to experience the large number of compounds you could make from a formula with few atoms.

Suggested solution

We give twelve possible structures – there are of course many more. You need not have used the names in brackets as they are ones more experienced chemists might use.
alkyne, primary amine
primary alcohol

(cyclic) amide
(lactam)

ketone, alkene,
primary amine (enamine)

ether, alkene
secondary amine

(cyclic) tertiary amine
aldehyde

alkene, amine, alcohol
(cyclic hydroxylamine)

(cyclic) ketone
primary amine

oxime
amine and alcohol

ether, nitrile

primary alcohol,
nitrile

imine, ether
(isoxazoline)

alkene, primary amide
Suggested solutions for Chapter 3

PROBLEM 1

Assuming that the molecular ion is the base peak (100% abundance) what peaks would appear in the mass spectrum of each of these molecules:

(a) C\textsubscript{2}H\textsubscript{5}BrO
(b) C\textsubscript{60}
(c) C\textsubscript{6}H\textsubscript{4}BrCl

In cases (a) and (c) suggest a possible structure of the molecule. What is (b)?

Purpose of the problem

To give you some practice with mass spectra and, in particular, at interpreting isotopic peaks. The molecular ion is the most important ion in the spectrum and often the only one that interests us.

Suggested solution

Bromine has two isotopes, \textsuperscript{79}Br and \textsuperscript{81}Br in about a 1:1 ratio. Chlorine has two isotopes \textsuperscript{35}Cl and \textsuperscript{37}Cl in about a 3:1 ratio. There is about 1.1% \textsuperscript{13}C in normal compounds.

(a) C\textsubscript{2}H\textsubscript{5}BrO will have two main molecular ions at 124 and 126. There will be very small (2.2%) peaks at 125 and 126 from the 1.1% of \textsuperscript{13}C at each carbon atom.

(b) C\textsubscript{60} has a molecular ion at 720 with a strong peak at 721 of 60 x 1.1 = 66%, more than half as strong as the \textsuperscript{12}C peak at 720. This compound is buckminsterfullerene.

(c) This compound is more complicated. It will have a 1:1 ratio of \textsuperscript{79}Br and \textsuperscript{81}Br and a 3:1 ratio of \textsuperscript{35}Cl and \textsuperscript{37}Cl in the molecular ion. There are four peaks from these isotopes (ratios in brackets) C\textsubscript{6}H\textsubscript{4}\textsuperscript{79}Br\textsuperscript{35}Cl (3), C\textsubscript{6}H\textsubscript{4}\textsuperscript{81}Br\textsuperscript{35}Cl (3), C\textsubscript{6}H\textsubscript{4}\textsuperscript{79}Br\textsuperscript{37}Cl (1), and C\textsubscript{6}H\textsubscript{4}\textsuperscript{81}Br\textsuperscript{37}Cl (1), the masses of these peaks being 190, 192, 192, and 194. So the complete molecular ion will have three main peaks at 190, 192, and 194 in a ratio of 3:4:1 with peaks at 191, 193, and 194 at 6.6% of the peak before it.

Compounds (a) and (c) might be isomers of compounds such as these:

\[\text{Br} \quad \text{OH} \quad \begin{array}{c} \text{Br} \\ \text{Cl} \end{array} \quad \begin{array}{c} \text{Br} \\ \text{Br} \end{array} \quad \begin{array}{c} \text{Cl} \\ \text{Br} \end{array}\]
PROBLEM 2
Ethyl benzoate PhCO₂Et has these peaks in its ¹³C NMR spectrum: 17.3, 61.1, 100–150 (four peaks) and 166.8 ppm. Which peak belongs to which carbon atom? You are advised to make a good drawing of the molecule before you answer.

Purpose of the problem
To familiarize you with the four regions of the spectrum.

Suggested solution
It isn’t possible to say which aromatic carbon is which and it doesn’t matter. The rest are straightforward.

PROBLEM 3
Methoxatin was mentioned on page 44 of the textbook where we said ‘it proved exceptionally difficult to solve the structure by NMR.’ Why is it so difficult? Could anything be gained from the ¹³C or ¹H NMR? What information could be gained from the mass spectrum and the infra red?

Purpose of the problem
To convince you that this structure really needs an X-ray solution but also to get you to think about what information is available by the other methods. Certainly mass spectroscopy, NMR, and IR would have been tried first.

Suggested solution
There are only two hydrogens on carbon atoms and they are both on aromatic rings. There are only two types of carbon atom: carbonyl groups and unsaturated ring atoms. This information is mildly interesting but is essentially negative—it tells us what is not there but gives us no information on the basic skeleton, where the carboxylic acids are, nor does it reveal the 1,2-diketone in the middle ring.
The mass spectrum would at least give the molecular formula C₁₄H₆N₂O₈ and the infra-red would reveal an N–H group, carboxylic acids, and perhaps the 1,2-diketone. The X-ray was utterly convincing and the molecule has now been synthesized, confirming the structure.

![Chemical structure diagram](image)

**PROBLEM 4**

The solvent formerly used in some correcting fluids is a single compound C₂H₃Cl₃, having¹³C NMR peaks at 45.1 and 95.0 ppm. What is its structure? How would you confirm it spectroscopically? A commercial paint thinner gives two spots on chromatography and has¹³C NMR peaks at 7.0, 27.5, 35.2, 45.3, 95.6, and 206.3 ppm. Suggest what compounds might be used in this thinner.

**Purpose of the problem**

To start you on the road to structure identification with one very simple problem and some deductive reasoning. It is necessary to think about the size of the chemical shifts to solve this problem.

**Suggested solution**

With the very small molecule C₂H₃Cl₃ it is best to start by drawing all the possible structures. In fact there are only two.

![Chemical structures](image)

The first would have a peak for the methyl group in the 0–50 region and one for the CCl₃ group at a very large chemical shift because of the three chlorine atoms. The second isomer would have two peaks in the 50–100 region, not that far apart. The second structure looks better but it would be easily confirmed by proton NMR as the first structure would have one peak only but the second would have two peaks for different CHs. The solvent is indeed the second structure 1,1,2-trichloroethane.

Two of the peaks (45.3 and 95.6) in the paint thinner are much the same as those for this compound (chemical shifts change slightly in a mixture as...
the two compounds dissolve each other). The other compound has a carbonyl group at 206.3 and three saturated carbon atoms, two close to the carbonyl group (larger shifts) and one further away. Butanone fits the bill perfectly. You were not expected to decide which CH₂ group belongs to which molecule—that can be found out by running a spectrum of pure butanone.

PROBLEM 5
The ‘normal’ O–H stretch in the infrared (i.e. without hydrogen bonding) comes at about 3600 cm⁻¹. What is the reduced mass (μ) for O–H? What happens to the reduced mass when you double the mass of each atom in turn, i.e. what is μ for O–D and what is μ for S–H? In fact, both O–D and S–H stretches come at about 2,500 cm⁻¹. Why?

Purpose of the problem
To get you thinking about the positions of IR bands in terms of the two main influences: reduced mass and bond strength.

Suggested solution
Using the equation on page 64 of the textbook we find that the reduced mass of OH is 16/17 or about 0.94. When you double the mass of H, the reduced mass of OD becomes 32/18 or about 1.78—nearly double that of OH. But when you double the mass of O, the reduced mass of SH is 32/33 or about 0.97—hardly changed from OH! The change in the reduced mass from OH to OD is enough to account for the change in stretching frequency—a change of about √2. But the change in reduced mass from OH to SH cannot account for the change in frequency. The explanation is that the S–H bond is weaker than the O–H bond by a factor of about 2. So both both O–D and S–H absorb at about the same frequency.

There is an important principle to be deduced from this problem. Very roughly, all the reduced masses of all bonds involving the heavier elements (C, N, O, S etc.) differ by relatively small amounts and the differences in stretching frequency are mainly due to changes in bond strength, though it can be significant in comparing, say, C–O with C–Cl. With bonds involving hydrogen the reduced mass becomes by far the most important factor.
**Problem 6**

Three compounds, each having the formula $\text{C}_3\text{H}_5\text{NO}$, have the IR data summarized here. What are their structures? Without $^{13}\text{C}$ NMR data it might be easier to draw some or all possible structures before trying to decide which is which. In what ways would $^{13}\text{C}$ NMR data help?

(a) One sharp band above 3000 cm$^{-1}$ and one strong band at about 1700 cm$^{-1}$

(b) Two sharp bands above 3000 cm$^{-1}$ and two bands between 1600 and 1700 cm$^{-1}$

(c) One strong broad band above 3000 cm$^{-1}$ and a band at about 2200 cm$^{-1}$

**Purpose of the problem**

To show that IR alone does have some use but that NMR data are usually essential as well. In answers to exam questions of this type it is important to show how you interpret the data as well as to give a structure. If you get the structure right, this doesn’t matter, but if you get it wrong, you may still get credit for your interpretation.

**Suggested solution**

(a) One sharp band above 3000 cm$^{-1}$ must be an N–H and one strong band at about 1700 cm$^{-1}$ must be a carbonyl group. That leaves $\text{C}_2\text{H}_4$, so we might have one of the structures shown below, though other less likely structures are possible too. $^{13}\text{C}$ NMR data would help as it would definitely show two types of saturated carbon (along with the carbonyl group) for the first compound, but only one for the second.

(b) Two sharp bands above 3000 cm$^{-1}$ must be an NH$_2$ group and two bands between 1600 and 1700 cm$^{-1}$ suggest a carbonyl group and an alkene. This leaves us with three hydrogen atoms so we must have something like the molecules below. $^{13}\text{C}$ NMR data would help as it would show an alkene carbon shifted downfield by being joined to electronegative nitrogen in the second case.

(c) One strong broad band above 3000 cm$^{-1}$ must be an OH group and a band at about 2200 cm$^{-1}$ must be a triple bond, presumably CN as otherwise

---

You will meet other ways of distinguishing these compounds in chapters 13 and 18.
we have nowhere to put the nitrogen atom. This means structures of this sort.

![N-containing structures]

**PROBLEM 7**
Four compounds having the formula C₄H₆O₂ have the IR and NMR data given below. How many DBEs (double bond equivalents—see p. 75 in the textbook) are there in C₄H₆O₂? What are the structures of the four compounds? You might again find it useful to draw a few structures to start with.

(a) IR: 1745 cm⁻¹; ¹³C NMR 214, 82, 58, and 41 ppm
(b) IR: 3300 cm⁻¹ (broad); ¹³C NMR 62 and 79 ppm.
(c) IR: 1770 cm⁻¹; ¹³C NMR 178, 86, 40, and 27 ppm.
(d) IR: 1720 and 1650 cm⁻¹ (strong); ¹³C NMR 165, 133, 131, and 54 ppm.

**Purpose of the problem**
First steps in identifying a compound from two sets of data. Because the molecules are so small (only four carbon atoms) drawing out a few trial structures is a good way to start.

**Suggested solution**
Here are some possible structures for C₄H₆O₂. It is clear that there are two double bond equivalents and that double bonds and rings are likely to feature. Functional groups are likely to include alcohol, aldehyde, ketone and carboxylic acid.

![Possible structures]

(a) IR: 1745 cm⁻¹ must be a carbonyl group; ¹³C NMR 214 must be an aldehyde or ketone, 82 and 58 look like two carbons next to oxygen and 41 is a carbon not next to oxygen but not far away. As the second oxygen doesn’t show up in the IR, it must be an ether. As there is only one double bond, the compound must be cyclic. This suggests just one structure.

(b) IR: 3300 cm⁻¹ (broad) must be an OH; ¹³C NMR 62 and 79 show a symmetrical molecule and no C=O so it must have a triple bond and a saturated carbon next to oxygen. This again gives only one structure.
(c) IR: 1770 cm\(^{-1}\) must be some sort of carbonyl group; \(^{13}\)C NMR 178 suggests an acid derivative, 86 is a saturated carbon next to oxygen, 40 and 27 are saturated carbons not next to oxygen. There is only one double bond so it must be a ring. Looks like a close relative of (a).

(d) IR 1720 and 1650 cm\(^{-1}\) (strong) must be C=C and C=O; \(^{13}\)C NMR 165 is an acid derivative, 131 and 133 must be an alkene, and 54 is a saturated carbon next to oxygen. That defines all the carbon atoms. It is not significant that we cannot say which alkene carbon is which.

PROBLEM 8
You have dissolved tert-butanol in MeCN with an acid catalyst, left the solution overnight, and found crystals in the morning with the following characteristics. What are the crystals?

IR: 3435 and 1686 cm\(^{-1}\); \(^{13}\)C NMR: 169, 50, 29, and 25 ppm; \(^1\)H NMR: 8.0, 1.8, and 1.4 ppm; Mass spectrum (%): 115 (7), 100 (10), 64 (5), 60 (21), 59 (17), 58 (100), and 56 (7). Don’t try to assign all the peaks in the mass spectrum.

Purpose of the problem
This is a common situation: you carry out a reaction and find a product that is not starting material, but what is it? You’ll need to use all the information and some logic. What you must not do is to decide in advance what the product is from your (limited) knowledge of chemistry and make the data fit.

Suggested solution
The molecular ion in the mass spectrum is 115 and is presumably C\(_6\)H\(_{13}\)NO—the sum of the two reagents t-BuOH and MeCN. It appears that they have added together but the IR shows that neither OH nor CN has survived. So what do we know?

- The IR tells us we have an N–H and a C=O group, accounting for both heteroatoms.
- The \(^{13}\)C NMR shows a carbonyl group (169) and three types of saturated carbon.
• There must be a lot of symmetry, suggesting that the t-Bu group has survived.

This leaves four fragments: NH, C=O, Me, and t-Bu, confirmed also by the 1H NMR spectrum, which tells us that we have three types of H atoms. We can join these fragments up in two ways:

\[
\begin{align*}
\text{O} & \quad \text{Me} \\
\text{N} & \quad \text{Me} \\
\text{O} & \quad \text{Me}
\end{align*}
\]

We might prefer the second as it retains the skeleton of MeCN, but a better reason is the base (100%) peak in the mass spectrum at 58. This is Me₂C=NH₂⁺ which could easily come from the second structure but only by extensive reorganization of the first structure.

The second structure is in fact correct but we need further analysis of the proton NMR (chapter 13) to be sure.

PROBLEM 9

How many signals would you expect in the 13C NMR spectrum of these compounds?

![Diagram of compounds A, B, C, D, and E]

**Purpose of the problem**

To get you thinking about symmetry.

**Suggested solution**

Compound A has tetrahedral symmetry and there are only two types of carbon: every CH₂ is the same, as is every CH, so it has two signals. This is the famous compound adamantane—a crystalline solid in spite of its being a hydrocarbon with only ten carbon atoms. If you do not see the symmetry, make a model—it is a beautiful structure.
Compound B is symmetrical too: the two C=O groups are the same and so are all the other carbon atoms in the ring. It is an orange crystalline solid called quinone. Two signals.

Compound C is naphthalene and has high symmetry: the two benzene rings are the same and there are only three types of carbon atom. Three signals.

Compound D is ‘triethanolamine’ used a lot by biochemists. It has threefold symmetry and only two types of carbon atom. Two signals.

Compound E is ‘EDTA’ (ethylenediaminetetraacetic acid) an important chelating agent for metals. This time there are three types of carbon atom. Three signals.
PROBLEM 10
When benzene is treated with tert-butyl chloride and aluminium trichloride, a crystalline product A is formed that contains only C and H. Mass spectrometry tells us the molecular mass is 190. The $^1$H NMR spectrum looks like this:

If crystals of A are treated again with more tert-butyl chloride and aluminium chloride, a new oily compound B may be isolated, this time with a molecular mass of 246. Its $^1$H NMR spectrum is similar to that of A, but not quite the same:

What are the two compounds? How many signals do you expect in the $^{13}$C NMR spectrum of each compound?

Purpose of the problem
Identifying compounds from spectroscopic data, whether you know the reaction or not, is a key skill you must develop.
Suggested solution

The $^1$H NMR spectrum is so simple that both compounds must have a lot of symmetry. Each of the two signals is in a different region of the spectrum (see p. 60 of the textbook), so both compounds have one type of H attached to sp$^2$-hybridized C atoms (presumably from the benzene starting material) and one type of H attached to sp$^3$-hybridized C atoms (presumably from the tert-butyl chloride starting material).

Often a good place to start with this sort of problem is to use the molecular mass to work out approximately how many of each of the starting molecules have been incorporated into the product: benzene has a mass of 78 and the tert-butyl group a mass of 57 (the chloride must be lost as there is no chlorine in the product), so it looks as though A is made up from one benzene molecule plus two tert-butyl groups and B from one benzene molecule and three tert-butyl groups (with loss of two or three hydrogen atoms where the tert-butyls are bonded to the benzene ring).

So, the only question left is how the substituents are arranged. Two tert-butyl groups could be arranged ortho, meta or para to each other, but only the para arrangement is possible for A because only when the two groups are para are all the protons of the aromatic ring identical (check for yourself).

With three tert-butyl groups, there are three possible arrangements (again, draw them for yourself to check), but as before only one of these allows all the protons on the benzene ring to be identical, each sandwiched between two tert-butyl groups. We have our structures for A and B. Both of them will show four signals in the $^{13}$C NMR spectrum, two of them between 100 and 150 ppm (C atoms in aromatic rings) and two of them between 0 and 50 ppm (saturated C atoms).
This page intentionally left blank
Suggested solutions for Chapter 4

**PROBLEM 1**
Textbooks sometimes describe the structure of sodium chloride like this ‘an electron is transferred from the valence shell of a sodium atom to the valence shell of a chlorine atom.’ Why would this not be a sensible way to make sodium chloride?

**Purpose of the problem**
To make you think about genuine ways to make compounds rather than theoretical ways.

**Suggested solution**
Of course sodium chloride consists of arrays of sodium cations without their 2s electron and chloride anions that have eight electrons in the 2s and 2p orbitals, but that is not how sodium chloride is made. Sodium atoms are present in sodium metal but where would you get the chlorine atoms? Mixing sodium and chlorine (Cl₂) would undoubtedly give sodium chloride but these are two aggressive reagents that would probably explode. Indeed, you would be more likely to make sodium and chlorine by the electrolysis of sodium chloride than the other way round. In any case, why make sodium chloride? Salt mines and the oceans are full of it.

**PROBLEM 2**
The H–C–H bond angle in methane is 109.5°. The H–O–H bond angle of water is close to this number but the H–S–H bond angle of H₂S is near 90°. What does this tell us about the bonding in water and H₂S? Draw a diagram of the molecular orbitals in H₂S.

**Purpose of the problem**
An exploration of hybridization.

**Suggested solution**
If the bond angle in water is close to the tetrahedral angle of perfectly symmetrical methane, water must be more or less tetrahedral (with respect to the arrangement of its electrons) too. We can think of the 2s and 2p electrons in water as hybridized into four pairs of electrons, two in H–O
bonds and two as lone pairs on the oxygen atom. But H₂S has a near right angle for its H–S–H bond. This suggests that the bonds are formed with p orbitals on the sulfur atom and that H₂S is not hybridized. Orbital diagram of H₂S: you might have drawn something like this:

PROBLEM 3
Though the helium molecule He₂ does not exist (p. 91 of the textbook explains why), the cation He₂⁺ does exist. Why?

Purpose of the problem
To encourage you to think about the filling of molecular orbitals and to accept surprising conclusions.

Suggested solution
He₂ does not exist because the number of anti-bonding electrons is the same as the number of bonding electrons. The bond order is zero. But if we remove an electron from the diagram on p. 91 of the textbook we have He₂⁺, with two bonding electrons and only one anti-bonding electron. The bond order is one half. He₂⁺ does exist.
**PROBLEM 4**
Construct an MO diagram for LiH and suggest what type of bond it might have.

**Purpose of the problem**
To demonstrate that a simple MO treatment can be applied to ionic as well as covalent structures.

**Suggested solution**
H has of course only one electron in a 1s orbital. Li has three – a full 1s shell and one electron in the 2s orbital. Li is very electropositive so its 2s orbital is high in energy—much higher than that of the 1s orbital of H. An electron is more stable in the 1s orbital of H than in the 2s orbital of Li, and the molecule is ionic. Both ions have the same electronic configuration: 1s^2.

**PROBLEM 5**
What is the hybridization and shape of each carbon atom in these molecules?

**Purpose of the problem**
To give you practice at selecting the correct hybridization of carbon atoms.

**Suggested solution**
Simply count the number of σ-bonds at each carbon atom (not forgetting the hydrogens that may not be shown). Two σ-bonds means sp and linear, three means sp^2 and trigonal, and four means sp^3 and tetrahedral. In each case the bonds stay as far from each other as they can.
PROBLEM 6
Draw detailed structures for these molecules and predict their shapes. We have deliberately made non-committal drawings to avoid giving away the answer to the question. Don’t use these sorts of drawings in your answer.

\[
\text{CO}_2, \text{CH}_2=\text{NCH}_3, \text{CHF}_3, \text{CH}_2=\text{C}=\text{CH}_2, (\text{CH}_2)_2\text{O}
\]

**Purpose of the problem**
To give you practice at selecting the right hybridization state for carbon atoms and translating this information into three-dimensional structures for the molecules.

**Suggested solution**
Carbon dioxide is linear as it has only two C–C σ-bonds and no lone pairs on C. The C atom must be sp hybridized and the only trick is to get the two π-bonds orthogonal to each other. They must be like that because the p orbitals on C used to make the two π-bonds are themselves orthogonal (p\(_x\) and p\(_y\)). Most people draw the O atoms as sp\(^2\) hybridized rather than sp or even unhybridized but this doesn’t matter as you really can’t tell.

The imine has a C=\(\text{N}\) double bond so it must have sp\(^2\) hybridized C and N. This means that the lone pair on nitrogen is in an sp\(^2\) orbital and not in a p orbital. The molecule is planar (except for the methyl group which is, of course, tetrahedral) and is bent at the nitrogen atom.
Trifluoromethane is, of course, tetrahedral with an sp\(^3\) hybridized carbon atom. The arrangement of the lone pairs round the fluorine (not shown) can also be assumed to be tetrahedral.

The next molecule CH\(_2\)=C=CH\(_2\) is allene and it has the same shape as CO\(_2\), and for the same reasons. We can now be sure that the end carbons are sp\(^2\) hybridized as they are planar, with the hydrogen substituents at 120° to each other and to the rest of the molecule. As with CO\(_2\), the two π bonds are orthogonal, meaning that the planes of the two terminal carbon atoms are also orthogonal, meaning that the molecule as a whole is not planar.

Finally, (CH\(_2\))\(_2\)O must be a three-membered ring and therefore the C–C–O skeleton must be planar (three points are always in a plane!). The two carbon atoms are sp\(^3\) hybridized (four σ bonds) and are tetrahedral (though very distorted as the ring angle is 60°) with the H atoms above and below the ring. The oxygen atom is presumably also sp\(^3\) hybridized, but it’s hard to tell experimentally.

**Problem 7**

Draw the shapes, showing estimated bond angles, of the following molecules:
(a) hydrogen peroxide, H\(_2\)O\(_2\)
(b) methyl isocyanate CH\(_3\)NCO
(c) hydrazine, NH\(_2\)NH\(_2\)
(d) diimide, N\(_2\)H\(_2\)
(e) the azide anion, N\(_3^-\)

**Purpose of the problem**

To think about shape and bond angles at elements other than carbon.
Suggested solution

Hydrogen peroxide, $\text{H}_2\text{O}_2$, has only single bonds: each oxygen atom has two lone pairs and the electron pairs, both bonding and non-bonding, are arranged tetrahedrally. The bond angles at oxygen will be approximately the tetrahedral angle of 109°.

In methyl isocyanate, $\text{CH}_3\text{NCO}$, the interesting atoms are the N and the C. The N atom must have a double bond to C, for which it must use a p orbital, leaving an s and two p orbitals for the remainder of the electrons. The N atom is sp² and trigonal, with one lone pair, so the bond angle at N is about 120°. The C atom is double bonded to both N and O, so the C atom is like the one in CO₂—linear, and sp hybridized.

In hydrazine, $\text{NH}_2\text{NH}_2$, there are only single bonds: both nitrogens are like amine nitrogens, pyramidal and sp³ hybridized.

In diimide the only reasonable structure has a double bond between the two nitrogen atoms, HN=NH, making the nitrogens trigonal (they must use a p orbital to make this double bond, leaving an s and two p orbitals for the remainder of the bonding, i.e. they are sp² hybridized). Each nitrogen is trigonal, with 120° bond angles. An interesting point about diimide is that, like an alkene, it can have a cis and a trans isomer.

Bonding in the azide anion $\text{N}_3^-$ is identical with that in carbon dioxide: the two molecules are isoelectronic (count the electrons to make sure). The central nitrogen is sp hybridized and linear.

**PROBLEM 8**

Where would you expect to find the lone pairs in (a) water, (b) acetone ($\text{Me}_2\text{C}=\text{O}$), and (c) nitrogen ($\text{N}_2$)?

**Purpose of the problem**

More thinking about the arrangements of electrons at O and N. The location of lone pairs might not seem easy to determine, but it affects the way that molecules form coordination complexes, for example.

**Suggested solution**

The oxygen atom of water is surrounded by eight electrons in two bonding and two non-bonding orbitals: it is sp³ hybridized and the electron pairs are
arranged tetrahedrally, so the lone pairs point towards the remaining two vertices of a tetrahedron.

In acetone, the oxygen atom must use one of its p orbitals to form the \( \pi \) bond to carbon, so it is left with an s and two p orbitals to accommodate the six electrons making up the \( \sigma \) bond to C and the two lone pairs. These three electron pairs are presumably arranged trigonally, so the lone pairs will lie in the plane of the carbonyl group, about 120° apart.

The two nitrogen atoms of \( \text{N}_2 \) each need two of their p orbitals to form the two \( \pi \) bonds, so they are left with one s and one p orbital for the two remaining electron pairs: the \( \sigma \) bond and the lone pair. The nitrogen atoms are sp hybridized and the lone pairs are 180° from the other N.
This page intentionally left blank
**Suggested solutions for Chapter 5**

**PROBLEM 1**

Each of these molecules is electrophilic. Identify the electrophilic atom and draw a mechanism for a reaction with a generalized nucleophile \( \text{Nu}^- \), giving the structure of the product in each case.

![Chemical structures](image)

**Purpose of the problem**

The recognition of electrophilic sites is half the battle in starting to understand mechanisms.

**Suggested solution**

We have two cations, two carbonyl compounds and two compounds with \( \sigma \)-bonds only. One of the cations has three bonds to a positively charged carbon so that is the electrophilic site as it has an empty orbital. The nucleophile will attack here.

![Mechanism diagram](image)

The other cation has a three-valent oxygen atom that cannot be the electrophilic site. The nucleophile must attack the proton instead. Some nucleophiles might attack the carbon atom joined to the cationic oxygen.

![Mechanism diagram](image)

The two carbonyl compounds will be attacked at the carbonyl group by the nucleophile. In general, \( \pi \)-bonds are more easily broken than \( \sigma \)-bonds and the negative charge goes on to the electronegative oxygen atom. In fact these anions will not be the final products of the reactions. As we will explore in more detail in later chapters, the first will pick up a proton to give an alcohol but the second might decompose with the release of the stable carboxylate anion.
The remaining electrophiles have σ-bonds only, one of which must break. Chlorine is symmetrical so it doesn’t matter which end you attack. You have more choice with MeSCl but the stability of the chloride ion wins the day: attack occurs at sulfur.

PROBLEM 2

Each of these molecules is nucleophilic. Identify the nucleophilic atom and draw a mechanism for a reaction with a generalized nucleophile $E^+$, giving the structure of the product in each case.

Purpose of the problem

The recognition of nucleophilic sites is the other half of the battle in starting to understand mechanisms.

Suggested solution

This time there are three anions but two of them (the alkyne and the sulfur anions) have lone pair electrons. We should start our arrows from the negative charges and they are the points of attachment of the electrophile in the product.
The third anion is like the borohydride anion discussed on p. 119 of the textbook. The negative charge does not represent a pair of electrons on Al: all the electrons are in the Al–H bonds and we must start our arrow from one of those. The nucleophilic site is a hydrogen atom.

The remaining nucleophiles have lone pairs. The nitrogen-containing molecule is hydrazine: both nitrogens are the same, and the product is positively charged, so it will lose a proton to become more stable.

The phosphorus compound has four atoms with lone pairs, the P and three O atoms. The lone pairs on oxygen are in lower energy orbitals than the one on phosphorus (P is lower down the periodic table and less electronegative than O), so it is the lone pair on P that reacts. The product is positively charged but this time it can’t lose a proton.

**PROBLEM 3**

Complete these mechanisms by drawing the structure of the product(s).

**Purpose of the problem**

Practice in interpreting curly arrows and drawing the products. Once the arrows are drawn, there is no more scope for decision making, so just draw the products.
Suggested solution

Just break the bonds that are broken and make the bonds that are being formed. Don’t forget to put in any charges and make sure you have neither created nor destroyed charge overall. You might straighten out the products a bit so that there are no funny angles.

\[
\text{PROBLEM 4}
\]
Put in the curly arrows on these starting materials to show how the product is formed. The compounds are drawn in a convenient arrangement to help you.

Purpose of the problem

To encourage you to be prepared to try and draw mechanisms for reactions you have never seen and to show you how easy it is.

Suggested solution

Just work out which bonds are lost and which are formed and draw arrows out of the one into the space for the other. Start your arrows on a source of electrons: an oxyanion in both these cases. End your arrows on an electronegative atom: oxygen in the first and bromine in the second example here.
Don’t worry if your arrows are not exactly the same as ours – so long as they start and finish in the right place they're all right. The notes on the mechanisms are just to help you see what is going on: you would not normally include them. The second reaction looks more complicated than the first but it is actually easier: just move electrons through the molecule.

**PROBLEM 5**

Draw mechanisms for the reactions in the following sequence.

- \( \text{I} \xrightarrow{\text{NaOH}} \text{OH} \xrightarrow{\text{NaH}} \text{O}^- \)
- \( \text{PhCH}_2\text{Br} \xrightarrow{} \text{O}^- \text{Ph} \)

**Purpose of the problem**

Practice in drawing curly arrows for a simple sequence of reactions.

**Suggested solution**

First look for the bond being broken and the bond being formed. In the first reaction, the weak C–I bond is breaking and a C–O is forming. The new OH group must come from the hydroxide, so here we have our nucleophile: HO\(^-\). The electrophile is the alkyl iodide. Make your first arrow start on a source of electrons in the nucleophile—in this case that has to be the hydroxide's negative charge. Those electrons make the new C–O bond, so send them towards C. The old C–I bond must break at the same time, forming an iodide anion.
In the next step, we just lose H, or rather H⁺, from the hydroxyl group. Sodium hydride is the reagent, and hydride is a base. Bases are just nucleophiles which attack H, so we can start our arrow on the negative charge again, attack H and break the H–O bond, pushing the electrons onto oxygen to make the anion. You need to draw out the bond between O and H to represent this mechanism clearly. The other product is of course gaseous hydrogen.

In the final step, the oxyanion must act as the nucleophile and the electrophile is benzyl bromide. The arrows start on the negative charge, and show the new C–O bond forming and the old C–Br bond breaking.

**PROBLEM 6**

Each of these electrophiles could react with a nucleophile at one of (at least) two atoms. Identify these atoms and draw a mechanism and products for each reaction.

**Purpose of the problem**

Considering possible alternative reactions. One of the reactions might seem trivial, but it isn’t.

**Suggested solution**

In each case one of the electrophilic sites is an acidic proton. There is also the electrophilic π bond (C=N⁺ or C=O). For the first case, we draw the two reactions separately.
In case you were seduced by the positively charged nitrogen atom (we hope you weren’t), we should also remind you of a reaction that most definitely cannot happen: direct attack at N: the supposed product has an impossible five bonds to nitrogen.

In the second compound there are three possibilities. The acidic proton of the carboxylic acid and the electrophilic C=O bond are both possible reaction sites, but now so is the positively charged phosphorus. Phosphorus comes below nitrogen in the periodic table so, unlike N, it can have five bonds.
PROBLEM 7
These three reactions all give the products shown, but not by the mechanisms drawn! For each mechanism, explain what is wrong, and draw a better one.

Purpose of the problem
Getting a feel for how you can, and can’t, use curly arrows to represent mechanisms.

Suggested solution
In the first reaction, the nucleophile is the amine and the electrophile is the methyl iodide, so the arrow is right in the sense that it starts on the nucleophile, where the electrons come from. However, we have stressed that a curly arrow should start on a representation of an electron pair, in other words on a lone pair, a bond or a negative charge. Here the arrow just starts on an atom: this is no good, and we must draw in the lone pair. The other problem is at the end of the arrow. It shows a new bond being formed to C, so unless a bond breaks then the C atom will have an impossible five bonds. We need another arrow to show the C–I bond breaking.
In the second reaction we form a cation by attack of a proton on an alkene. Which is the nucleophile? It can’t be H⁺: by definition a proton can’t have a pair of electrons! The arrow must therefore start on the alkene and show the electrons moving towards the proton, not the other way round. The electrons come from the π bond, so the double bond is where we start the arrow. We only need one arrow, because as the new C–H bond forms, the C atom at other end of the old π bond is left with only 6 electrons, and becomes positively charged.

The last reaction forms a new S–Cl bond. The arrow we have drawn starts on a lone pair, but if electrons are moving from Cl to S, surely the S will become negatively charged? The mistake is that the arrow is the wrong way round: the sulfur atom is the nucleophile, and the more electronegative chlorine is the electrophile. Start the arrow on the sulfur lone pair, and break the old Cl–Cl bond as the electrons arrive at Cl.

**PROBLEM 8**

In your corrected mechanisms for problem 7, explain in each case which orbital is the HOMO of the nucleophile and which orbital is the LUMO of the electrophile.

**Purpose of the problem**

Reinforcing the link between curly arrows and molecular orbitals.

**Suggested solution**

The nucleophilic amine of the first reaction uses its lone pair to form the new bond: the HOMO is the sp³ orbital containing this non-bonding electron pair. The empty orbital used by the electrophile must be an antibonding orbital, since as the electrons arrive there they cause the C–I bond to break: the LUMO is the C–I σ* orbital.

When the alkene is protonated, it loses its π bond, and we have already pointed out that the electrons must come from this bond (that’s why we
start the arrow there). So the HOMO is the C=C π orbital. The LUMO is the only orbital the H⁺ ion has available: its empty 1s orbital.

In the third reaction, the LUMO of the electrophile is easy to spot: it must be the Cl–Cl σ* orbital, since that is the bond that breaks. The nucleophile uses the lone pair on sulfur to react, so the HOMO is the non-bonding orbital occupied by this lone pair.

**PROBLEM 9**

draw a mechanism for the following reaction. (This is harder, but if you draw out the structures of the reactants first, and consider that one is an acid and one is a base, you will make a good start.)

\[
\text{PhCHBrCHBrCO}_2\text{H} + \text{NaHCO}_3 \rightarrow \text{PhCH=CHBr} + \text{NaHCO}_3
\]

**Purpose of the problem**

Working out the mechanism for a more difficult transformation.

**Suggested solution**

Working out the structure of the starting material, even through it’s written very unhelpfully, is straightforward if you take into account the fact that each carbon has four substituents. Bicarbonate is a base, so you expect the carboxylic acid to be deprotonated to form a carboxylate anion.

![Structure](image)

Now for the real reaction. Looking at the product tells us we have to lose CO₂, along with one of the bromine atoms, so the bonds that have to break are the ones shown in the structure above. The best thing to do in this case is to start ‘pushing arrows’—one of the reasons they are so powerful is they often lead you through to the product. Start at the obvious place—the negative charge—and be guided by the bonds that have to break and form.

![Mechanism](image)

Everything works and the electrons end up happily on a bromide anion.
Suggested solutions for Chapter 6

**PROBLEM 1**

Draw mechanisms for these reactions:

1. \( \text{NaBH}_4 \xrightarrow{\text{EtOH, H}_2\text{O}} \text{CHO} \)
2. \( \text{LiAlH}_4 \xrightarrow{\text{1. LiAlH}_4, \text{2. H}_2\text{O}} \text{OH} \)

**Purpose of the problem**

Rehearsal of a simple but important mechanism that works for all aldehydes and ketones.

**Suggested solution**

Draw out the BH\(_4\) and AlH\(_3\) anions, with the carbonyl compound positioned so that one of the hydrogens can be transferred to the carbonyl group, and then transfer the hydrogen from B or Al to C. A proton transfer is needed to make the alcohol: from the solvent in the first case and during the work-up with water in the second.

This reaction shows that you can reduce aldehydes with lithium aluminium hydride, even if you would usually prefer the more practical sodium borohydride.
PROBLEM 2

Cyclopropanone exists as the hydrate in water but 2-hydroxyethanal does not exist as the hemiacetal. Explain.

Purpose of the problem
To get you thinking about equilibria and hence the stability of compounds.

Suggested solution
Hydration is an equilibrium reaction so the mechanism is not strictly relevant to the question, though there is no shame in including mechanisms whenever you can. To answer the question we must consider the effect of the three-membered ring on the relative stability of starting material and product. All three-membered rings are very strained because the bond angles are 60° instead of 109° or 120°. Cyclopropanone is particularly strained because the sp² carbonyl carbon would like a bond angle of 120°—there is ‘60° of strain.’ In the hydrate that carbon atom is sp³ hybridized and so there is only about ‘49° of strain.’ Not much gain, but the hydrate is more stable than the ketone.

The second case is totally different. The hydroxy-aldehyde is not strained at all but the hemiacetal has ‘49° of strain’ at each atom. Even without strain, hydrates and hemiacetals are usually less stable than their aldehydes or ketones because one C=O bond is worth more than two C–O bonds. In this case the hemiacetal is even less stable and, unlike the cyclopropanone, can escape strain by breaking a C–O ring bond.
PROBLEM 3
One way to make cyanohydrins is illustrated here. Suggest a detailed mechanism for the process.

Purpose of the problem
To help you get used to mechanisms involving silicon and revise an important way to promote additions to the carbonyl group.

Suggested solution
The silyl cyanide is an electrophile while the cyanide ion in the catalyst is the nucleophile. Cyanide adds to the carbonyl group and the oxyanion product is captured by silicon, liberating another cyanide ion for the next cycle.

PROBLEM 4
There are three possible products from the reduction of this compound with sodium borohydride. What are their structures? How would you distinguish them spectroscopically, assuming you can isolate pure compounds?

Purpose of the problem
To let you think practically about reactions that may give more than one product.

Suggested solution
The three compounds are easily drawn: one or other carbonyl group, or both, may be reduced.
The third compound, the diol, has no carbonyl group in the $^{13}$C NMR spectrum or the infrared and has a molecular ion two mass units higher than the other two products. Distinguishing those is more tricky, and needs techniques you will meet in detail in chapter 18. The hydroxyketone has a conjugated carbonyl group (C=O stretch at about 1680 cm$^{-1}$ in the infrared spectrum) while the hydroxyaldehyde is not conjugated (C=O stretch at about 1730 cm$^{-1}$ in the infrared). The chemical shift of the C–OH carbons will also be different because the benzene ring is joined to this carbon in the aldehyde but not in the ketone.

**PROBLEM 5**

The triketone shown here is called ‘ninhydrin’ and is used for the detection of amino acids. It exists in aqueous solution as a hydrate. Which ketone is hydrated and why?

**Purpose of the problem**

To let you think practically about reactions that may give more than one product.

**Suggested solution**

The two ketones next to the benzene ring are stabilized by conjugation with it but also destabilized by the central ketone—two electron-withdrawing groups next to each other is a bad thing. The central carbonyl group is not stabilized by conjugation and is destabilized by two other ketones so it forms the hydrate. Did you remember that hydrate formation is thermodynamically controlled?
**PROBLEM 6**

This hydroxyketone shows no peaks in its infrared spectrum between 1600 and 1800 cm\(^{-1}\), but it does show a broad absorption at 3000–3400 cm\(^{-1}\). In the \(^{13}\)C NMR spectrum there are no peaks above 150 ppm but there is a peak at 110 ppm. Suggest an explanation.

**Purpose of the problem**

Structure determination to solve a conundrum.

**Suggested solution**

The evidence shows that there is no carbonyl group in the molecule but that there is an OH group. The peak at 110 ppm looks at first sight like an alkene, but it could also be an unusual saturated carbon atom bonded to two oxygens. You might have argued that an alcohol and a ketone could combine to give a hemiacetal, and that is, of course, just what it is. The compound exists as a stable hemiacetal because it has a favourable five-membered ring.

P. 136 of the textbook explains why cyclic hemiacetals are stable.
PROBLEM 7
Each of these compounds is a hemiacetal and therefore formed from an alcohol and a carbonyl compound. In each case give the structures of the original materials.

Purpose of the problem
To give you practice in seeing the underlying structure of a hemiacetal.

Suggested solution
Each OH group represents a carbonyl group in disguise (marked with a grey circle). Just break the bond between this carbon and the other oxygen atom and you will see what the hemiacetal was made from. The first example shows how it is done.

The next is similar but the alcohol is a different molecule.

Do not be deceived by the third example. There is one hemiacetal (two oxygens joined to the same carbon atom) but the other OH is just a tertiary alcohol.
The last two examples are not quite the same. The first is indeed symmetrical but the second has one oxygen atom in a different position so that there is only one hemiacetal. Note that these hemiacetals may not be stable.

PROBLEM 8
Trichloroethanol may be prepared by the direct reduction of chloral hydrate in water with sodium borohydride. Suggest a mechanism for this reaction. Take note that sodium borohydride does not displace hydroxide from carbon atoms!

Purpose of the problem
To help you detect bad mechanisms and find concealed good ones.

Suggested solution
If sodium borohydride doesn’t displace hydroxide from carbon atoms, then what does it do? We know it attacks carbonyl groups to give alcohols and to get trichloroethanol we should have to reduce chloral. Hemiacetals are in equilibrium with their carbonyl equivalents, so...

[Diagram of reactions involving chloral hydrate and trichloroethanol]
PROBLEM 9
It has not been possible to prepare the adducts from simple aldehydes and HCl. What would be the structure of such compounds, if they could be made, and what would be the mechanism of their formation? Why can’t these compounds be made?

Purpose of the problem
More revision of equilibria to help you develop a judgement on stability.

Suggested solution
This time we need a mechanism so that we can work out what would be formed. Protonation of the carbonyl group and then nucleophilic addition of chloride ion would give the supposed products.

There’s nothing wrong with the mechanism, it’s just that the reaction is an equilibrium that will run backwards. Hemiacetals are unstable because they decompose back to carbonyl compounds. Chloride ion is very stable and decomposition will be faster than it is for hemiacetals.

PROBLEM 10
What would be the products of these reactions? In each case give a mechanism to justify your prediction.

Purpose of the problem
Giving you practice in the art of predicting products—more difficult than simply justifying a known answer.

Suggested solution
The Grignard reagent will add to the carbonyl group and the work-up will give a tertiary alcohol as the final product.
The second reaction should give you brief pause for thought as you need to recall that borohydride reduces ketones but not esters.
This page intentionally left blank
PROBLEM 1
Are these molecules conjugated? Explain your answer in any reasonable way.

Purpose of the problem
Revision of the basic kinds of conjugation and how to show conjugation with curly arrows.

Suggested solution
The first compound is straightforward with one conjugated system (an enone) and a non-conjugated alkene. You could draw curly arrows to show the conjugation, like this, and/or give a diagram to show the distribution of the electrons.

The last three compounds obviously form a related group with the same skeleton and only the alkene moved round. There is of course ester conjugation in all three and this is the only conjugation in the last molecule. The first has extended conjugation between the nitrogen lone pair and the carbonyl group and the second has simple conjugation between the alkene and the ester.
The only conjugation in the last compound is the delocalization of the ester oxygen lone pair. This is of course there in all the other compounds too.

PROBLEM 2
How extensive is the conjugated system(s) in these compounds?

Purpose of the problem
To explore more extensive conjugated systems.

Suggested solution
Both compounds are completely conjugated: even including the nitrogen atom in the first and the carbonyl group in the second. You can draw the arrows going either way round the ring to give different ways of writing the same structure. The arrows on the second compound should end on the carbonyl oxygen.
PROBLEM 3
Draw diagrams to represent the conjugation in these molecules. Draw two types of diagram:
(a) Show curly arrows linking at least two different ways of representing the molecule
(b) Indicate with dotted lines and partial charges (where necessary) the partial double bond (and charge) distribution.

Purpose of the problem
A more exacting exploration of the precise details of conjugation.

Suggested solution
Treating each compound separately in the styles demanded by the question, the first (the guanidinium ion) is a very stable cation because of conjugation. The charge is delocalized onto all three nitrogen atoms as the first three structures show. Each nitrogen has an equal positive charge so our fourth diagram shows one third + on each.

The second compound is what you will learn to call an enolate anion. The negative charge is delocalized throughout the molecule, mostly on the oxygens but some on carbon. It is difficult to represent this with partial charges but the charges on the oxygens will be nearly a half each.
The third compound is naphthalene. The structure drawn in the question is the best as both rings are benzene rings. The results of curly arrow diagrams show how naphthalene is delocalized all round the outer ring. In fact these diagrams show the ten electrons in the outer ring – this is a $4n + 2$ number and all three diagrams show that naphthalene is aromatic.

**PROBLEM 4**

Draw curly arrows linking alternative structures to show the delocalization in
(a) diazomethane $\text{CH}_2\text{N}_2$
(b) nitrous oxide, $\text{N}_2\text{O}$
(c) dinitrogen tetroxide, $\text{N}_2\text{O}_4$

**Purpose of the problem**

Delocalization in some neutral molecules we nonetheless have to draw using charges.

**Suggested solution**

You saw on page 154 of the textbook that the nitro group, although it is neutral, can be represented as a pair of delocalized structures containing charges. The same is true for the explosive gas diazomethane. It has a linear structure, and we can draw two alternative structures, both with charges, even though it is a neutral compound. They’re linked with the double headed arrow used for alternative representations for the same compound. We hope you remembered to avoid the trap of giving nitrogen five bonds!

Nitric oxide is very similar—in fact it is isoelectronic with diazomethane. You can think of it as a nitrogen molecule in which an oxygen atom has captured one of the lone pairs.

Dinitrogen tetroxide is a gas which decomposes to the more familiar brown air pollutant nitrogen dioxide ($\text{NO}_2$) at higher temperatures. The
only way we can draw it seems most unsatisfactory: both nitrogens with positive charges! Even though these are not full positive charges, and this molecule does bring into focus the inadequacy of some valence bond representations, perhaps our discomfort with the structure is an indication of why this N–N bond is so weak…

PROBLEM 5
Which (parts) of these compounds are aromatic? Justify your answer with some electron counting. You may treat rings separately or together as you wish. You may notice that two of them are compounds we met in problem 2 of this chapter.

Purpose of the problem
A simple exploration of the idea of aromaticity: can you count up to six? Remember: count only those $\pi$ electrons in the ring and on no account put one electron on both atoms at either end of the bond: put the electrons where they are—in the bond.

Suggested solution
The numbers show how many $\pi$ electrons there are in each bond or at each atom. The first compound has a lone pair on nitrogen in a p-orbital shared between both rings. Each ring has six electrons and the periphery of the whole molecule has ten electrons. Both rings and the entire molecule are aromatic. The second has four $\pi$ electrons only so there is no aromaticity anywhere. The third has six $\pi$ electrons in the ring including the lone pair...
on oxygen but not including the carbonyl group which is outside the ring. The compound is aromatic.

For the rest we have put the number of $\pi$ electrons inside each ring and there are two aromatic rings in each compound. Again we don’t count carbonyl group electrons as they are outside the ring. So one ring in aklavinone has only four electrons and is not aromatic while one of the seven-membered rings in colchicine is aromatic. Each compound has one saturated ring that cannot be aromatic.

**PROBLEM 6**

The following compounds are considered to be aromatic. Account for this by identifying the appropriate number of delocalized electrons.

**Purpose of the problem**

Accounting for aromaticity in less familiar circumstances.

**Suggested solution**

Indole, as drawn here, has eight double bonds, which give eight delocalized electrons. To be aromatic, it needs $2n+2$, so two more electrons must come from the lone pair of the nitrogen atom.
Azulene is isomeric with naphthalene, and it’s quite easy to find the ten electrons – four in one ring and six in the other.

Pyridone has six electrons—two from the double bonds in the ring and two from nitrogen. That means that the carbonyl group, whose double bond is not part of the ring, does not contribute to the aromatic sextet. This is generally true for double bonds which stick out of the ring—see problem 2.

Adenine is one of the four bases which carry the genetic code in DNA. Its ten electrons arise as shown: eight from the double bonds and two from one of the nitrogen atoms in the five-membered ring. The other three nitrogens don’t contribute their lone pairs, because they are not delocalized—like the lone pair in pyridine.
PROBLEM 7

Cyclooctatetraene (see p. 158 of the textbook) reacts readily with potassium metal to form a salt, K₂[cyclooctatetraene]. What shape do you expect the ring to have in this compound? A similar reaction of hexa(trimethylsilyl)benzene with lithium also gives a salt. What shape do you expect this ring to have?

Purpose of the problem

The consequences of aromaticity and 'antiaromaticity'.

Suggested solution

Cyclooctatetraene, as explained on p. 158 of the textbook, is 'tub-shaped' and not planar, because its eight π electrons do not form a 2n+2 number. However, two atoms of potassium can reduce the cyclooctatetraene to a dianion by giving it two electrons, so now it has ten electrons, is aromatic, and is planar. Just one of the many possible delocalized structures of the product is shown here.

When lithium reduces hexa(trimethylsilyl)benzene, the aromatic sextet is increased to a total of eight delocalized electrons, so the compound is no longer aromatic. The six membered ring in the salt is no longer flat.
**PROBLEM 8**
How would you expect the hydrocarbon below to react with bromine, Br₂?

![Diagram of a hydrocarbon reacting with bromine](image)

**Purpose of the problem**
The consequences of aromaticity for reactivity.

**Suggested solution**
Aromatic rings typically react by substitution, so that they can retain the aromatic sextet. By contrast, alkenes react by electrophilic addition—the classic test for an alkene is that they decolourize bromine water. So, how will our hydrocarbon (known as indene) react? It contains an aromatic ring, but the five-membered ring is not aromatic—it contains a saturated carbon atom. So there is a choice of substitution on the six-membered ring or addition to the alkene in the five-membered ring. Alkenes are more reactive than benzene, so the alkene reacts first:

![Product of addition to the alkene](image)

**PROBLEM 9**
In aqueous solution, acetaldehyde (ethanal) is about 50% hydrated. Draw the structure of the hydrate of acetaldehyde. Under the same conditions, the hydrate of N,N-dimethylformamide is undetectable. Why the difference?

![Structures of acetaldehyde and N,N-dimethylformamide](image)

**Purpose of the problem**
The consequences of delocalization for reactivity.
Suggested solution

As you saw in chapter 6, aldehydes are readily hydrated. For amides, however, there is a price to pay: the delocalization that contributes to the stability of the amide would be lost on hydration, so dimethylformamide is not hydrated in aqueous solution.
Suggested solutions for Chapter 8

**PROBLEM 1**
How would you separate a mixture of these three compounds?

- Naphthalene
- Pyridine
- Para-toluic acid

**Purpose of the problem**
Revision of simple acidity and basicity in a practical situation.

**Suggested solution**
Pyridine is a weak base (pKₐ of the pyridinium ion is about 5.5) and can be dissolved in aqueous acid. Naphthalene is neither an acid nor a base and is not soluble in water at any pH. para-Toluic acid is a weak acid (pKₐ about 4.5) and can be dissolved in aqueous base. So dissolve the mixture in an organic solvent immiscible with water (say ether Et₂O or dichloromethane CH₂Cl₂) and extract with aqueous acid. This will dissolve the pyridine as its cation. Then extract the remaining organic layer with aqueous base such as NaHCO₃ which will remove the toluic acid as its water-soluble anion. You now have three solutions. Evaporate the organic solution to give crystalline naphthalene. Acidify the basic solution of para-toluic acid and the free acid will precipitate out and can be recrystallized. Add base to the pyridine solution, extract the pyridine with an organic solvent, and distil the pyridine. It doesn’t matter if you extract the original solution with base first and acid second.

**PROBLEM 2**
In the separation of benzoic acid from toluene on p. 164 of the textbook we suggested using KOH solution. How concentrated a solution would be necessary to ensure that the pH was above the pKₐ of benzoic acid (4.2)? How would you estimate how much KOH solution to use?

**Purpose of the problem**
To ensure you understand the relationship between pH and concentration.
Suggested solution

Even a very weak solution of KOH has a pH>4.2. If we want a pH of 5 (just above the pKₐ of benzoic acid) we must ensure that we have [H₃O⁺] = 10⁻⁵ mol dm⁻³. The ionic product of water is [H₃O⁺] x [HO⁻] = 10⁻¹⁴ and so we need 10⁻⁹ mol dm⁻³ of KOH. This is very dilute! The trouble would be that you need one hydroxide ion for each molecule of benzoic acid and so if you had, say, 1.22 g PhCO₂H (= 0.01 equiv.) you would need 1000 litres (dm³) of KOH solution. It makes more sense to use a much more concentrated solution, say 0.1M. This would give an unnecessarily high pH (13) but you would need only 100 ml (0.1 dm³) to extract your benzoic acid.

PROBLEM 3

What species would be present in a solution of this hydroxy-acid in (a) water at pH 7, (b) aqueous alkali at pH 12, and (c) in concentrated mineral acid?

Purpose of the problem

To get you thinking about what really is present in solution using rough pKₐ as a guide in a practical situation.

Suggested solution

The CO₂H group will have a pKₐ of about 4–5 and the phenolic OH a pKₐ of about 10. So the carboxylic acid but not the phenol will be ionized at pH 7, they will both be ionized at pH 12, and there will be a mixture of free acid and protonated acid at very low pH. The proton will be on the carbonyl oxygen atom as this gives a delocalized cation.

See page 173 of the textbook for the pKₐ of phenol.
PROBLEM 4
What would you expect to be the site of (a) protonation and (b) deprotonation if these compounds were treated with the appropriate acid or base? In each case suggest a suitable acid or base and give the structure of the products.

Purpose of the problem
Progressing to more taxing judgements on more interesting molecules.

Suggested solution
The simple amine piperidine will easily be protonated by even weak acids as the conjugate base has a pKₐ of about 11. Any mineral acid such as HCl will do the job as would weaker acids such as RCO₂H. Deprotonation will remove the NH proton as nitrogen is more electronegative than carbon but a very strong base such as BuLi will be needed as the pKₐ will be about 30–35. You could represent the product with an N–Li bond or as an anion.

The second example is more complicated but contains a normal tertiary amine so protonation will occur there with most acids as as the conjugate base has a pKₐ of about 11. We use TsOH this time but that has no special significance. The tertiary amine cannot be deprotonated and in any case the alcohol is more acidic and a strong base will be needed, say NaH.

The third example is more complicated still. There is a normal OH group (pKₐ of about 16) and a slightly acidic alkyne (pKₐ of about 32). The basic group is not a simple amine but a delocalized amidine. Protonation occurs
on the top (imine) nitrogen as the positive charge is then delocalized over both nitrogens. Protonation on the other nitrogen does not occur. The $pK_a$ of the conjugate base is about 12.

The first proton to be removed by base will be from the alcohol and this will need a reasonably strong base such as NaH. Removal of the alkyne proton requires a much stronger base such as BuLi. You might represent the product as an alkyne anion or a covalently bonded alkylolithium.

PROBLEM 5
Suggest what species would be formed by each of these combinations of reagents. You are advised to use estimated $pK_a$ values to help you and to beware of those cases where nothing happens.

(a) (b) (c)

Purpose of the problem
Learning to compare species of similar acidity or basicity.

Suggested solution
In each case one of the reagents might take a proton from the other. In example (a), would the phenolate anion remove a proton from acetic acid? The answer is yes because acetic acid is a much stronger acid than phenol. The difference is five pH units so the equilibrium constant would be about $10^5$ and the equilibrium would lie far across to the right.
Example (b) has a similar possible reaction but this time the $pK_a$ difference is much smaller and the other way so the equilibrium constant is 100 and favours the starting materials.

Example (c) is rather different. We do have another carboxylic acid but this is a much stronger acid because of the three fluorine atoms and the equilibrium is far over to the left.

PROBLEM 6
What is the relationship between these two molecules? Discuss the structure of the anion that would be formed by the deprotonation of each compound.

Purpose of the problem
To help you recognize that conjugation may be closely related to tautomerism.

Suggested solution
They are tautomers: they differ only in the position of one hydrogen atom. It is on nitrogen in the first structure and on oxygen in the second. As it happens the first structure is more stable. They are both aromatic (check that you see why) but the first has a strong carbonyl group while the second
has a weaker imine. Deprotonation may appear to give two different anions but they are actually the same because of delocalization. Note the different ‘reaction’ arrows: equilibrium sign for deprotonation and double headed arrow for delocalization.

PROBLEM 7

The carbon NMR spectrum of these compounds can be run in D₂O under the conditions shown. Why are these conditions necessary? What spectrum would you expect to observe?

Purpose of the problem

NMR revision and practice at judging the states of compounds at different pHs. Observation of hidden symmetry from conjugation.

Suggested solution

Both compounds are quite polar and not very soluble in the usual NMR solvents. In addition they have NH or OH protons that exchange in solution and broaden the spectrum. With acid or base catalysis the NH and OH protons are exchanged with deuterium and sharp signals appear. But in the strong acid or base used here, ions are formed. The first compound, a strongly basic guanidine (see p. 167 of the textbook) forms a cation in DCl. The cation is symmetrical, unlike the original guanidine, and a very simple spectrum results: just three types of carbon in the benzene ring and one very low field carbon (at large δ) for the carbon in the middle of the cation.

The second compound loses a proton from the OH group to give a delocalized symmetrical anion. There will be five signals in the NMR: the
two methyl groups are the same (at small δ) as are the two CH₂ groups in the ring (at slightly larger δ). There is one unique carbon joined to the two methyl groups (at small δ) and another in the middle of the anion (at large δ). Finally both carbonyl groups are the same (at even larger δ).

PROBLEM 8
These phenols have approximate pKₐ values of 4, 7, 9, 10, and 11. Suggest with explanations which pKₐ value belongs to which phenol.

Purpose of the problem
Detailed examination of electronic effects to estimate pKₐ values.

Suggested solution
Electron-withdrawing effects make phenols more acidic and electron-donating effects make them less acidic. Phenol itself (the fourth example) has a pKₐ of 10. The only compound less acidic than phenol must be the third with three weakly electron-donating methyl groups. One chlorine atom has an inductive electron-withdrawing effect so the last compound has pKₐ 9. The remaining two have the powerful electron-withdrawing nitro group. So the first compound, with two nitro groups, must have pKₐ of 4 (making it as strong an acid as acetic acid) and the second, with one nitro group, must have pKₐ of 7.
PROBLEM 9

The pH values of these two amino acids are as follows:

(a) cysteine: 1.8, 8.3, and 10.8
(b) arginine: 2.2, 9.0, and 13.2.

Assign these pH values to the functional groups in each amino acid and draw the most abundant structure that each molecule will have at pH 1, 7, 10, and 14.

Purpose of the problem

Further revision in thinking about acidity and basicity of functional groups, and reinforcement of expected pH values for functional groups. Amino acids are particularly important.

Suggested solution

At high pH cysteine exists as a dianion as both the thiol and the carboxylic acid are anions. If we now add acid, at about pH 10 (actually 10.8) the amine will get protonated, then the thiol will be protonated at about pH 8 (actually 8.3) and finally the carboxylic acid will be protonated at low pH, rather lower than say MeCO₂H, as the electron-withdrawing ammonium group increases its acidity (actually at 1.8).
At high pH arginine exists as a monoanion—even the very basic guanidine group cannot be protonated at pH 14. If we now add acid, at about pH 13 the guanidine will get protonated, then the amino group will be protonated at about pH 10 (actually 9.0) and finally the carboxylic acid will be protonated at low pH. This carboxylic acid is rather more acidic than you might expect, but not surprisingly it is harder to protonate an anion in a molecule which already has an overall positive charge.

PROBLEM 10
Neither of these two methods for making pentan-1,4-diol will work. What will happen instead?

Purpose of the problem
To help you appreciate the disastrous effects that innocent-looking groups may have because of their weak acidity.
Suggested solution

The OH group is the Wicked Witch of the West in this problem. Whoever planned these syntheses expected it to lie quietly and do nothing. All chemists have to learn that things don’t go our way just because we want them to do so. Here, although the OH group is only a weak acid (pKₐ about 16) it will give up its proton to the very basic Grignard reagents. In the first case, one molecule of Grignard is destroyed but the reaction might succeed if two equivalents were used.

![Chemical structure 1]

The second case is hopeless as the Grignard reagent destroys itself by intramolecular deprotonation. This synthesis could be rescued by putting a protecting group on the OH.

![Chemical structure 2]

PROBLEM 11

Which of these bases would you choose to deprotonate the following molecules? Very strong bases are more challenging to handle so you should aim to use a base which is just strong enough for the job, but not unnecessarily strong.

![Chemical structures 3]

Choice of bases:

KOH NaH BuLi NaHCO₃

Purpose of the problem

To help you match basicity to acidity—an important part of choosing reagents for many reactions.
Suggested solution

We can start by estimating the $pK_a$ of the most acidic proton in each of the substrates to be deprotonated, and likewise estimating the $pK_a$ of the conjugate acids of the proposed bases. Most of these values were discussed in chapter 8, and you were encouraged to commit some of them to memory.

Any of the bases will deprotonate compounds above and to the left of them. So, to deprotonate the least acidic of these, the amine, you would choose to use butyllithium. To deprotonate the alkyne (a reaction which is commonly used to make C–C bonds) you could use BuLi, or alternatively sodium hydride (NaH). BuLi has to be handled under an inert atmosphere, while NaH, although it reacts with water, can be spooned out safely as a suspension in oil.

The alcohol has a $pK_a$ close to that of water, so hydroxide is not a good choice for complete deprotonation, and sodium hydride is commonly used for this purpose. Hydroxide will however deprotonate both the carboxylic acid, to make a carboxylate salt, or the ammonium ion, to make the free amine. Bicarbonate is also commonly used for this purpose: although it is only just basic enough to do the job, the deprotonation reaches completion because it is not an equilibrium: protonated bicarbonate forms carbonic acid which decomposes irreversibly to water and carbon dioxide.
This page intentionally left blank
Suggested solutions for Chapter 9

**PROBLEM 1**
Propose mechanisms for the first four reactions in the chapter.

1. **PhMgBr**
   - 1. \( \text{PhMgBr} \rightarrow \text{HO Ph} \)
   - 2. \( \text{H}^+, \text{H}_2\text{O} \rightarrow \text{HO Ph} \)

2. **Li**
   - 1. \( \text{Li} \rightarrow \text{HO Ph} \)
   - 2. \( \text{H}^+, \text{H}_2\text{O} \rightarrow \text{HO Ph} \)

3. **MgCl**
   - 1. \( \text{MgCl} \rightarrow \text{HO H} \)
   - 2. \( \text{H}^+, \text{H}_2\text{O} \rightarrow \text{HO H} \)

4. **Li**
   - 1. \( \text{Li} \rightarrow \text{HO H} \)
   - 2. \( \text{H}^+, \text{H}_2\text{O} \rightarrow \text{HO H} \)

**Purpose of the problem**
Rehearsal of the basic mechanisms from chapter 9.

**Suggested solution**
Each reaction involves nucleophilic attack of the organometallic reagent on the aldehyde or ketone followed by protonation. You may draw the intermediate as an anion or with an O–metal bond as you please. Note the atom-specific arrows to show which atom is the nucleophile. In the third reaction the allyl-Li might attack through either end.
PROBLEM 2

What products would be formed in these reactions?

Purpose of the problem

The toughest test: predicting the product. The sooner you get practice the better.

Suggested solution

Though prediction is harder than explanation, you should get these right the first time as only the last one has a hint of difficulty. In the first example, the ethyl Grignard reagent acts as a base to remove a proton from the alkyne. Whether you draw the intermediate as an alkyne anion or a Grignard reagent is up to you. Notice that sometimes we give the protonation step at the end and sometimes not. This is the general practice among organic chemists and you may or you may not bother to draw the mechanism of this step.
For the second example, just make the organometallic reagent and add it to the carbonyl group. Cyclobutanone is more electrophilic than many other ketones because of the strain of a carbonyl group in a four-membered ring. This time the protonation is shown.

The third example raises the question of which halogen is replaced. In fact bromine is more easily replaced than chlorine. Iodine is more easily replaced than either and fluorine usually does not react. Don’t be disappointed if you failed to see this.

PROBLEM 3
Suggest alternative routes to fenarimol different from the one in the textbook on p. 192. Remind yourself of the answer to problem 2 above.

Purpose of the problem
Practice in choosing alternative routes.

Suggested solution
Three aromatic rings are joined to a tertiary alcohol in fenarimol, so the alternatives are to make organometallic reagents from different aromatic compounds. Two aromatic compounds must be joined to form a ketone and the third added as an organometallic reagent. You will meet ways to make ketones like these in chapter 21. You’ll need the insight from problem 2 above to help you choose Br as the functional group to be lithiated or converted into a Grignard reagent. Here are two possible methods:
PROBLEM 4
Suggest two syntheses of the bee pheromone heptan-2-one.

Purpose of the problem
Further exploration of the use of organometallic compounds. This time you'll probably need the oxidation of alcohols from p. 194 of the textbook.

Suggested solution
There are of course many different solutions but the most obvious are to make the corresponding secondary alcohol and oxidize it. Two alternatives are shown here.
PROBLEM 5
The antispasmodic drug biperidin is made by the Grignard addition reaction shown here. What is the structure of the drug? Do not be put off by the apparent complexity of the structure: just use the chemistry of Chapter 9.

\[
\begin{align*}
\text{Br} & \quad \text{1. Mg, Et}_2\text{O} \quad \text{biperidin} \\
& \quad \text{2.} \\
\end{align*}
\]

How would you suggest that the drug procyclidine should be made?

Purpose of the problem
Exercise in product prediction in a more complicated case and a logical extension to something new.

Suggested solution
A Grignard reagent must be formed from the alkyl bromide and this must add to the ketone. Aqueous acidic work up (not mentioned in the problem as is often the case) must give a tertiary alcohol and that is biperidin.

To get procyclidine, we must change both the alkyl halide and the ketone but the reaction is very similar.
PROBLEM 6
The synthesis of the gastric antisecretory drug rioprostil requires this alcohol.

(a) Suggest possible syntheses starting from ketones and organometallics.
(b) Suggest possible syntheses of the ketones in part (a) from aldehydes and organometallics (don’t forget about CrO₃ oxidation).

Purpose of the problem
Your first introduction to sequences of reactions where more complex molecules are created.

Suggested solution
There are three one-step syntheses from ketones and organometallic compounds. We have used ‘M’ to indicate the metal—it might be Li or MgX (in other words, the organometallic could be an organolithium or a Grignard reagent).

Each of these ketones can be made by oxidation of an alcohol that can in turn be made from an organometallic compound and an aldehyde.
PROBLEM 7
Why is it possible to make the lithium derivative A by Br/Li exchange, but not the lithium derivative B?

Purpose of the problem
Revision of the stability of carbanions and its relevance to lithium/bromine exchange.

Suggested solution
The first example is a vinyl bromide and vinyl (sp²) carbanions are more stable than saturated (sp³) carbanions because of the greater s-character in the C–Li bond. The second example is saturated, like BuLi, but it is a tertiary alkyl bromide. The t-alkyl carbanion would be less stable than the primary one and its lithium derivative less stable than BuLi, so it is not formed.
**PROBLEM 8**

How could you use these four commercially available starting materials to make the following three compounds?

\[ \text{PhCHO} \quad \text{EtI} \quad \text{CO}_2 \quad \text{Br} \]

![Chemical structures](image)

**Purpose of the problem**

Thinking about synthesis: how to put molecules together

**Suggested solution**

The first compound contains a phenyl and an ethyl group, so you could convert the ethyl iodide to a Grignard reagent and add it to the aldehyde. The product is an alcohol, so you need to use \( \text{CrO}_3 \) to oxidize it to the ketone.

![Synthesis reaction](image)

The second compound is a carboxylic acid, which can come from addition of the Grignard reagent derived from cyclopentyl bromide to carbon dioxide.

![Synthesis reaction](image)

The third compound is a tertiary alcohol, which you could make by addition of the same cyclopentyl Grignard reagent to a ketone. The ketone will also need to be made by oxidation of an alcohol, itself derived from benzaldehyde and the cyclopentyl Grignard reagent.

![Synthesis reaction](image)
Suggested solutions for Chapter 10

**PROBLEM 1**

Suggest reagents to make the drug phenaglycodol by the route below.

Purpose of the problem

Simple revision of addition to carbonyl groups from chapter 6.

Suggested solution

The first step is a simple addition of cyanide to a ketone (p. 127 of the textbook) usually carried out with NaCN and an acid, such as acetic acid. The second step is an acid-catalysed addition of an alcohol to a nitrile (p. 213 of the textbook). Finally there is a double addition of an organometallic reagent to an ester (p. 216 of the textbook). One way of doing all this is shown below.
**PROBLEM 2**

Direct ester formation from carboxylic acids \((R^1\text{CO}_2\text{H})\) and alcohols \((R^2\text{OH})\) works in acid solution but not in basic solution. Why not? By contrast, ester formation from alcohols \((R^2\text{OH})\) and acid anhydrides \([R^1\text{CO}_2\text{O}]\) or chlorides \((R^1\text{COCl})\) is commonly carried out in basic solution in the presence of bases such as pyridine. Why does this work?

**Purpose of the problem**

These questions may sound trivial but students starting organic chemistry often fall into the trap of trying to make esters from carboxylic acids and alcohols in basic solution. Thinking about the reasons may help you avoid this error.

**Suggested solution**

The direct reaction works in acid solution as the carboxylic acid is protonated (at the carbonyl group, note) and becomes a good electrophile. Later the tetrahedral intermediate is protonated and can lose a molecule of water.

In basic solution, the first thing that happens is the removal of the proton from the carboxylic acid to form a stable delocalized anion. Nucleophiles cannot attack this anion and no further reaction occurs.

Acid anhydrides and acid chlorides do not have this acidic hydrogen so the alcohol attacks them readily and the base is helpful in removing the acidic proton from the intermediate. The weak base pyridine (pKₐ of the conjugate acid 5.5) is ideal. The product from the uncatalysed reaction would be HCl from the acid chloride and the base also removes that.
PROBLEM 3
Predict the success or failure of these attempted substitutions at the carbonyl group. You should use estimated $pK_a$ values in your answer and, of course, draw mechanisms.

Purpose of the problem
A chance to try out the correlation between leaving group ability and $pK_a$ explained in the textbook (p. 205).

Suggested solution
You need to draw mechanisms for the formation of the tetrahedral intermediate and check that it is in the right protonated form. Then you need to check which potential leaving group is the best, using appropriate estimated $pK_a$ values. The first and the last proposals will succeed but the second will not as chloride ion is a better leaving group than even a protonated amine and this reaction would go backwards.
Solutions Manual to accompany Organic Chemistry

PROBLEM 4
Suggest mechanisms for these reactions.

Purpose of the problem
Drawing mechanisms for nucleophilic substitution on important compounds including cyclic and dicarbonyl compounds.

Suggested solution
In the first reaction there are two nucleophilic substitutions and you must decide which nucleophile attacks first. The amine is a better nucleophile than the alcohol. The cyclization occurs because, in the intermediate for the second substitution, there are two alcohols as potential leaving groups. Either can leave but when the ring opens again, the alcohol is still part of the molecule and will re-cyclize, but if the ethoxide leaves it is lost into solution and does not come back.
The second reaction is more straightforward. The amide proton is quite acidic and will be removed by the base making a better nucleophile. Notice that in these suggested solutions we are using the shorthand of the double-headed arrow on the carbonyl group.

**PROBLEM 5**

In making esters of the naturally occurring amino acids (general structure below) it is important to keep them as their hydrochloride salts. What would happen to these compounds if they were neutralized?

**Suggested solution**

The amino acids do not usually react with themselves as they exist mostly as the zwitterion. But after the acid is esterified it is much more electrophilic and the amino group is now nucleophilic.
The amine of one compound attacks the ester group of another to form a dimer (a peptide) which may cyclize to form a double amide, known as a diketopiperazine. The cyclization is usually faster than the dimerization as it is an intramolecular reaction forming a stable six-membered ring.

PROBLEM 6

It is possible to make either the diester or the monoester of butanedioic acid (succinic acid) from the cyclic anhydride as shown. Why does one method give the diester and one the monoester?

Purpose of the problem

An exploration of selectivity in carbonyl substitutions. Mechanistic thinking allows you to say confidently whether a reaction will happen or not. This problem builds on problem 2.

Suggested solution

In basic solution the nucleophile is methoxide ion. This strong nucleophile attacks the carbonyl group to give a tetrahedral intermediate having two possible leaving groups. The ester anion is preferred ($pK_a$ of RCO$_2$H about 5) to the alkoxide ion ($pK_a$ of ROH about 15). This carboxylate anion cannot be protonated in basic solution and is not attacked by methoxide ion.
In acid solution the first reaction is similar, though the tetrahedral intermediate is neutral, and the carboxyl is still the better leaving group. The second esterification is now all right because methanol can attack the protonated carboxylic acid and water can be driven out after a second protonation. The second step is an equilibrium, with water and methanol about equal as leaving groups, but methanol is present in large excess as the solvent and drives the equilibrium across. We have omitted proton transfer steps.

**PROBLEM 7**

Suggest mechanisms for these reactions, explaining why these particular products are formed.

**Purpose of the problem**

A contrast between very reactive (acid chloride), less reactive (anhydride) and unreactive (amide) carbonyl compounds.

**Suggested solution**

The acid chloride reacts rapidly with the water and the carboxylic acid produced reacts rapidly with a second molecule of acid chloride. The anhydride reacts much more slowly (pKₐ of HCl is –7 but the pKₐ of RCO₂H is about 5) with water so there is a good chance of stopping the reaction there, especially when we use a low concentration of water in acetone solution. In this instance the chance is made a certainty because the anhydride precipitates from the solution and is no longer in equilibrium.
with the other reagents. It is usually possible to descend the reactivity sequence of acid derivatives.

\[
\text{PhCl} \xrightarrow{\text{fast}} \text{PhCl} \xrightarrow{\text{fast}} \text{PhO} \xrightarrow{\text{OH}} \text{PhO}
\]

The second reaction is an example of the alkaline hydrolysis of amides. Though the nitrogen atom is never a good leaving group, it will leave from the dianion and, once gone, it is quickly protonated and does not come back. This example also benefits from the release of the slight strain in the five-membered ring.

**Purpose of the problem**

Analysis of a sequence of reactions where the first stops at the halfway stage but the second does not.

**Suggested solution**

One of the carbonyl groups of the anhydride must be attacked by LiAlH₄ and we need to follow that reaction through to see what happens next. The first addition of AlH₄⁻ produces a tetrahedral intermediate that decomposes with the loss of the only possible leaving group, the carboxylate ion, to give an aldehyde. That too is quickly reduced by AlH₄⁻ to give the hydroxy-acid as its anion, which is resistant to further reduction. In the acidic aqueous work-up, excess LiAlH₄ is instantly destroyed and the hydroxy-acid cyclizes to the lactone. The fact that the lactone is not formed under the reaction conditions is important: if it were, then it too would be reduced by the LiAlH₄.
The second reaction starts similarly with the Grignard reagent adding to the ester carbonyl group and the tetrahedral intermediate losing the only possible leaving group. Again, a reactive carbonyl compound is produced: a ketone that is more electrophilic than the ester, so it adds the Grignard reagent even faster. Work-up in aqueous acid gives the diol.

**PROBLEM 9**

This reaction goes in one direction in acid solution and in the other direction in basic solution. Draw mechanisms for the reactions and explain why the product depends on the conditions.

**Purpose of the problem**

A reminder that carbonyl substitutions are equilibria and that removal of a product from an equilibrium may decide which way the reaction goes. Practice at drawing mechanisms for intramolecular reactions.

**Suggested solution**

The equilibrium we are concerned with is that between the two products and we can draw what would happen in neutral solution.
The amine attacks the ester in the usual way to give the tetrahedral intermediate which decomposes with the loss of the better leaving group: phenols are reasonably acidic ($pK_a \text{ PhOH} = 10$) so the phenoxy anion is a much better leaving group than $\text{ArNH}^-$. In strongly basic solution, the phenol product is fully deprotonated, so again, the equilibrium lies to the right. In acidic solution the starting amine is fully protonated, pulling the equilibrium back over to the left.

\[ \text{NH}_2 \quad \text{O} \quad \text{NH}_3 \]

in acidic solution

\[ \text{NH}_2 \quad \text{O} \quad \text{NH}_3 \]

in basic solution

**PROBLEM 10**

Amelfolide is a drug used to treat cardiac arrhythmia. Suggest how it could be made from 4-nitrobenzoic acid and 2,5-dimethylaniline.

\[ \text{H}_2\text{N} \quad \text{amelfolide} \quad \text{O}_2\text{N} \quad \text{4-nitrobenzoic acid} \quad \text{O}_2\text{N} \quad \text{2,6-dimethylaniline} \]

**Purpose of the problem**

A reminder to avoid a common error in proposed reactions of carboxylic acids.

**Suggested solution**

It is tempting to try and react the amine directly with the acid, but unfortunately the only product this would give is the ammonium carboxylate salt: the amine deprotonates the acid, and the carboxylate anion that results is no longer electrophilic. With alcohols, esters can be formed from carboxylic acids under acid catalysis, but with amines the acid catalyst just protonates the amine, and it is no longer nucleophilic! The simplest
solution is to convert the carboxylic acid to an acid chloride and allow that to react with the amine. Additional base will neutralize the HCl by-product.

\[ \text{PhOH} + \text{PhNH}_2 \xrightarrow{\text{SOCl}_2} \text{PhOCl} + \text{PhNH}_3^+ \]

\[ \text{PhOCl} + \text{H}_2\text{N} \xrightarrow{\text{base}} \text{PhNHCOOH} \]

**PROBLEM 11**

Given that the $pK_a$ of tribromomethane, CHBr$_3$ (also known as bromoform) is 13.7, suggest what will happen when this ketone is treated with sodium hydroxide.

\[ \text{CHBr}_3 \]

**Purpose of the problem**

Predicting reactivity with an unusual leaving group.

**Suggested solution**

The best approach to new reactions is to start drawing curly arrows for steps you know are reasonable, and to see where they take you. Here, we are treating a carbonyl compound, an electrophile, with hydroxide, a nucleophile, so the first step is likely to be addition of hydroxide to the C=O group. You have seen many, many reactions that start this way.

\[ \text{CHBr}_3 \xrightarrow{\text{HO}^{-}} \text{CHB} + \text{HO}^{-} \]

\[ \text{CHB} + \text{H}_2\text{O} \xrightarrow{\text{pK}_a \text{ about 5}} \text{CHB}_2 + \text{H}_3\text{O}^+ \]
The result looks like a tetrahedral intermediate: the only possible leaving groups are the hydroxide (which takes us back to starting materials) or the anion Br₃C⁻. You learnt in chapter 10 to use pKₐ to estimate leaving group ability, so the relatively low value of 13.7 should encourage you to eject it, giving a carboxylic acid as well. Neutralization of the acid by the tribromomethyl anion gives the products—the carboxylate anion and tribromomethane.

**PROBLEM 12**

This sequence of reactions is used to make a precursor to the anti-asthma drug montelukast (Singulair). Suggest structures for compounds A and B.

**Purpose of the problem**

Deducing the presence of functional groups from mass and infra-red spectra.

**Suggested solution**

Lithium aluminium hydride reduces esters to alcohols, so the only question here is whether it reduces one, or both esters. The IR tells us that there is an alcohol (3600 cm⁻¹) and no carbonyl group (which you would expect around 1700 cm⁻¹) so we can assume that both esters have been reduced. The diol structure below is consistent with the mass of the molecular ion.

Alcohols react with acid chlorides to form esters, so again we have the choice between a single or double ester formation. The IR tells us that one of the alcohols is still present, along with a carbonyl at 1710 cm⁻¹, and the mass of the product is consistent with the structure below.
Suggested solutions for Chapter 11

PROBLEM 1

Draw mechanisms for these reactions, both of which involve loss of the carbonyl's oxygen atom.

Purpose of the problem

To see if you can draw mechanisms for two of the main classes of reactions in the chapter.

Suggested solution

As MeOH is present in large excess as the solvent, it probably adds first. This also makes the intermediate for the addition of chloride a stable oxonium ion. The mechanism is very like that for acetal formation and, if you added chloride first, that is also a reasonable mechanism.

The second example is imine formation—attack by an amine nucleophile and dehydration of the intermediate. Don’t forget to protonate the OH group so that it can leave as a water molecule.
PROBLEM 2
Each of these compounds is an acetal, that is a molecule made from an aldehyde or ketone and two alcohol groups. Which compounds were used to make these acetals?

Purpose of the problem
Practice at the recognition of acetals and working out how to make them.

Suggested solution
All we have to do is to identify the hidden carbonyl group by finding the only carbon atom having two C–O bonds. This atom is marked with a grey circle. If you imagine breaking the two C–O bonds you will discover the carbonyl group and the alcohols.
**PROBLEM 3**

Suggest mechanisms for these two reactions of the smallest aldehyde, formaldehyde (methanal CH$_2$=O).

**Purpose of the problem**

Extension of simple acetal chemistry into related reactions with nitrogen.

**Suggested solution**

Both reactions start in the same way by attack of a nitrogen nucleophile on formaldehyde. Acid catalysis is not necessary for this step. The first reaction ends with the formation of the iminium ion by acid-catalysed dehydration.

In the other reaction a second amino group is waiting to capture the iminium ion by cyclization to form a stable five-membered ring.
PROBLEM 4
In the textbook (p. 104) we showed you a selective hydrolysis of an acetal. Why were the other acetals (one is a thioacetal) not affected by this treatment? How would you hydrolyse them? Chloroform (CHCl₃) is the solvent.

Purpose of the problem
Revision of the different types of acetal and their relative reactivity.

Suggested solution
Cyclic acetals are more stable than non-cyclic ones as we explain on p. 228 of the textbook. Hydrolysis needs more vigorous conditions. Thioacetals are much harder to hydrolyse because sulfides are even less basic than ethers. They can be hydrolysed using electrophiles that attack sulfur readily, such as Hg(II) or methylating agents. This is one possible solution:
PROBLEM 5
In the textbook (p. 228) we say that the Grignard reagent below is ‘an unstable structure—impossible to make.’ Why is this? What would happen if you tried to make it?

![Chemical structure](image)

Purpose of the problem
Revision of the danger of mutually destructive functional groups.

Suggested solution
There are various possibilities that all arise from the presence of a carbonyl group and a Grignard in the same molecule. These two would react together. They might cyclize to form a four-membered ring or a bimolecular reaction might lead to a dimer and perhaps polymerization.

![Chemical structures](image)

PROBLEM 6
Suggest mechanisms for these reactions.

![Chemical structures](image)

Purpose of the problem
Extension of acetal and imine formation into examples where the intermediate is trapped by a different nucleophile.
Suggested solution

The first reaction starts with the usual attack of an alcohol on the aldehyde but the second nucleophile is the carboxylic acid. Though a poor nucleophile, it is good enough to react with an oxonium ion, particularly in a cyclization.

The second reaction starts with nucleophilic attack by the amine on the more electrophilic carbonyl group—the ketone. Imine formation is followed by cyclization and this second step is normal nucleophilic substitution of an ester (chapter 10). The imine double bond moves into the ring to secure conjugation with the ester.

The third example uses very simple molecules and again starts with imine formation. Cyanide is the nucleophile that captures the iminium ion and a second imine formation completes the mechanism.
PROBLEM 7

Don’t forget the problem in the summary on p. 238 of the textbook: suggest a mechanism for the formation of this thioacetal.

Purpose of the problem

Extension of the mechanism for acetal formation to dithioacetal (dithiane) formation.

Suggested solution

The mechanism is a direct analogue of acetal formation. The dehydration step is more difficult: the C=S bond is less stable than the C=O bond because overlap of 2p and 3p orbitals is not as good as overlap of two 2p orbitals of similar size and energy.
PROBLEM 8

In chapter 6 we described how the anti-leprosy drug dapsone could be made soluble by the formation of a ‘bisulfite adduct’. Now that you know about the reactions described in chapter 11, you should be able to draw a mechanism for this reaction. The adduct is described as a ‘prodrug’, meaning that it is not the drug but gives rise to the drug by chemistry within the body. How might this happen?

Purpose of the problem

Revision of chemistry from chapter 6 with a challenging mechanistic problem: did you avoid the trap?

Suggested solution

The trap is to go straight to the product by displacing hydroxide ion from the formaldehyde bisulfite adduct. Hydroxide is a very bad leaving group and reactions like this never occur.

To avoid this trap we must use carbonyl chemistry. First we must make formaldehyde from its adduct and add it to the amino group of dapsone.

Now we can form an iminium salt and add the bisulfite back into this reactive electrophile to give the final product. This is loss of carbonyl oxygen in an unusual setting as the carbonyl was not there at the start and is present only in the intermediates.
PROBLEM 9
This stable product can be isolated from the reaction between benzaldehyde and ammonia. Suggest a mechanism.

\[
\text{CHO} + \text{NH}_3 \xleftrightarrow{\text{H}_2\text{O}} \text{H}_2\text{O} + \text{NH} + \text{N}
\]

Purpose of the problem
Revision of aminal formation—the all-nitrogen version of acetal formation.

Suggested solution
Imine formation follows the usual pathway (pp. 230–32 of the textbook) but this imine is unstable, as are most primary imines, and it reacts with more benzaldehyde. This reaction starts normally enough but dehydration of the first intermediate produces a strange looking cation with two double bonds to the same nitrogen atom. Addition of another imine gives the final product. The benzene rings play no part in these reactions so we shall represent them as Ph, but they do stabilize the final product by conjugation with the imines.
**PROBLEM 10**

In the following scheme

(a) Identify the functional group in each molecule, and
(b) Suggest a reagent or reagents for carrying out each transformation represented by an arrow.

**Purpose of the problem**

Some important transformations of nitrogen containing functional groups.

**Suggested solution**

Primary amines are transformed into amides by substitution reactions of acid chlorides, and to imines by condensation with an aldehyde in the presence of an acid catalyst. Both amides and imines may be reduced to amines: amides need LiAlH₄ while imines may be reduced by sodium borohydride, sodium cyanoborohydride, or hydrogenation over a palladium catalyst.

Secondary amines react with aldehydes to form enamines, which may be reduced to amines by hydrogenation, or (via their iminium ion tautomer) with sodium borohydride or sodium cyanoborohydride.
PROBLEM 11

Three chemical steps convert cyclohexane-1,4-dione into a compound which is used for the synthesis of the anti-migraine drug frovatriptan. Suggest how this transformation is carried out.

Purpose of the problem

Designing a route to a real pharmaceutical target.

Suggested solution

Both carbonyl groups have undergone substitution. One of them is converted to an acetal, so we must treat the ketone with a diol and an acid catalyst. Primary amines are transformed into amides by substitution reactions of acid chlorides, and to imines by condensation with an aldehyde in the presence of an acid catalyst.

The other ketone must be converted into an amine, so we can use reductive amination: we could first make the imine with methylamine, and reduce it; alternatively we can use NaCNBH₃ to reduce the imine as it forms.
MeNH₂
NaCNBH₃
PROBLEM 1
In the comparison of stability of the last intermediates in the substitution at the carbonyl group of acid chlorides or anhydrides to make esters (chapter 10) we preferred one of these intermediates to the other:

Why is the one more stable than the other? If you were to treat an ester with acid, which of the two would be formed?

Purpose of the problem
Revision of contribution of delocalization to stability, particularly of cations.

Suggested solution
The positive charge on the more stable cation is delocalized over both oxygen atoms making it more stable than the other that has a localized cation on one oxygen atom. Protonation of the ester gives the more stable cation as both oxygens combine to make the carbonyl oxygen more nucleophilic.
PROBLEM 2
This reaction shows third-order kinetics as the rate expression is

$$\text{rate} = [\text{keto}ne][\text{HO}^-]^2$$

Suggest a mechanism for the reaction.

Purpose of the problem
Interpretation of unexpected kinetics to find a mechanism

Suggested solution
The hydroxide ion must attack the ketone to form a tetrahedral intermediate. The best leaving group from this intermediate is the hydroxide ion that has just come in (p$K_a$ of H$_2$O is about 15) rather than the alkyne anion. If we use the second hydroxide ion to deprotonate the intermediate, only one leaving group remains, though it is a poor one, and the decomposition of the dianion must be the rate-determining step. This mechanism is found for substitutions at the carbonyl group with very bad leaving groups, as in the hydrolysis of amides (p. 213 in the textbook).
PROBLEM 3
Draw an energy profile diagram for this reaction. You will of course need to draw the mechanism first. Suggest which step in this mechanism is likely to be the slow step and what kinetics would be observed

Purpose of the problem
Practice at drawing energy profile diagrams as one way to present the energetics of mechanisms.

Suggested solution
The first thing is to draw the mechanism of the reaction.

The first step is bimolecular and forms a new C–C bond. The second step is just a proton transfer between oxygen atoms and is certainly fast. The first step must be the rate-determining step and the intermediate must have a higher energy than the starting material or the product. In this answer we have used the style of energy-profile diagrams used in the textbook (e.g. p. 252) but there is nothing sacred about this—any similar diagram is fine.
PROBLEM 4

What would be the effect of solvent changes on these reactions? Would the reactions be accelerated or retarded by a change from a polar to a non-polar solvent?

Ph₃P \xrightarrow{Br_2, \text{solvent}} Ph₃P^\ominus - Br

O
\text{solvent} \quad O
\text{heat} \quad O
R
\xrightarrow{NH_3, \text{solvent}} R

Purpose of the problem

Practice at assessing the likely effect of solvent polarity in terms of the mechanism of the reaction.

Suggested solution

It is essential to draw a mechanism for each reaction and to identify the rate-determining step in each case. The first two reactions are one-step processes so that makes life easier.
Now we need to draw the transition state for each reaction so that we can assess whether it is more or less polar than the starting materials. The way to do this is described on p. 251 of the textbook.

\[
\begin{align*}
\text{Ph}_3\text{P} \rightleftharpoons \text{Br} \quad \text{Ph}_3\text{P} \rightleftharpoons \text{Br} \\
\text{NMe}_3 \quad \text{NMe}_3
\end{align*}
\]

In the first reaction uncharged starting materials form a partly charged transition state. A polar solvent will stabilize the transition state and accelerate the reaction. In the second case a charged (zwitterionic) starting material gives a partly charged transition state. A polar solvent will stabilize both starting material and transition state but it will stabilize the starting material more. The energy gap will increase and the reaction go more slowly.

The third reaction is different as it has more than one step. It is a carbonyl substitution of the kind we met in chapter 10. The nucleophile (ammonia) attacks the carbonyl group to form a tetrahedral intermediate that decomposes with the loss of the better leaving group.

\[
\begin{align*}
\text{R} \quad \text{OMe} \quad \text{O} \quad \text{NH}_3 \\
\text{R} \quad \text{OMe} \quad \text{O} \quad \text{NH}_3 \\
\end{align*}
\]

We have marked two steps ‘fast’ because they are just proton transfers between nitrogen and oxygen atoms. Either of the other two steps might be rate determining. In this substitution the leaving group is relatively good (compare problem 2) and the rate-determining step is the first: the usual one for carbonyl substitutions. In this step, neutral starting materials turn into a charged (zwitterionic) intermediate so the transition state is becoming charged and the reaction is accelerated by more polar solvents.

**PROBLEM 5**

Comment on the effect of acid and base on these equilibria.

**Purpose of the problem**

Practice at assessing how equilibrium constants respond to acid and base.
The mechanisms in acid and in base are described on p. 208 and p. 210 of the textbook.

**Suggested solution**

The first example is cyclic ester (lactone) formation that will go well in acid solution. In base the acidic proton will be removed and cyclization is no longer possible (see p. 210 in the textbook).

![Cyclic ester formation](image1)

The second example is cyanohydrin formation from a ketone (see p. 127 in the textbook). The reaction is reversible but in basic solution the cyanide anion is more stable than the oxyanion of the cyanohydrin and the carbonyl group is more stable than C–O plus C–C so the reaction runs backwards. In more acidic solution (pH less than about 12) the oxyanion will be protonated and the reaction driven towards the right.

![Cyanohydrin formation](image2)
PROBLEM 1
How many signals will there be in the \(^1\)H NMR spectrum of each of these compounds? Estimate the chemical shifts of the signals.

Purpose of the problem
Considering the effects of symmetry on proton (rather than carbon) NMR, and practice in estimating chemical shift.

Suggested solution
Considerations of symmetry apply equally to \(^1\)H and to \(^13\)C NMR. This is the answer, with different types of proton marked with different letters.

Estimating the chemical shift in \(^1\)H NMR requires you to modify your experience of \(^13\)C NMR to the narrower range of proton shifts and to consider that aromatic protons are in a distinct region from alkene protons. In each case we give a reasonable estimate and then the actual values. If your values agree with our estimates, you have done well. If you get something near the actual values, be very proud of yourself. The first compound has hydrogens on sp\(^3\) carbon atoms bonded to two nitrogen atoms—hence the very large shift. The fourth molecule has two methyl groups directly bonded to electropositive silicon—hence the very small shift. The rest are more easily explained.
PROBLEM 2

The following products might possibly be formed from the reaction of MeMgBr with the cyclic anhydride shown. How would you tell the difference between these compounds using IR and \(^{13}\)C NMR? With \(^1\)H NMR available as well, how would your task be easier?

Purpose of the problem

Further thinking the other way round—from structure to data. Contrasting the limitations of \(^{13}\)C NMR with data from \(^1\)H NMR spectra.

Suggested solution

The molecular formula of the compounds varies so a mass spectrum would be useful. The compounds with an OH group would show a broad U-shaped band at above 3000 cm\(^{-1}\). The cyclic ester would have a C=O stretch at about 1775 cm\(^{-1}\), the ketones at about 1715 cm\(^{-1}\), and the CO\(_2\)H group a band at about 1715 cm\(^{-1}\) as well as a very broad band from 2500 to 3500 cm\(^{-1}\). In the \(^{13}\)C NMR the acid and ester would have a carbonyl peak at about 170–180 ppm, but the ketones would have one at about 200 ppm. The number and position of the other signals would also vary.
Solutions for Chapter 13 – $^1$H NMR: proton nuclear magnetic resonance

In the proton NMR, all compounds would show two linked CH$_2$ groups as a pair of triplets except in the second compound as there the symmetry makes the two the same and would give a singlet. All except the second have a 6H singlet for the CMe$_2$ group. The second compound has two singlets because of the symmetry. The last has an isolated Me group. The OH and CO$_2$H protons might show up as broad signals at any chemical shift.

**PROBLEM 3**

One isomer of dimethoxybenzoic acid has the $^1$H NMR spectrum $\delta$ (ppm) 3.85 (6H, s), 6.63 (1H, t, $J$ 2 Hz), and 7.17 (2H, d, $J$ 2 Hz). One isomer of coumalic acid has the $^1$H NMR spectrum $\delta$ (ppm) 6.41 (1H, d, $J$ 10 Hz), 7.82 (1H, dd, $J$ 2, 10 Hz), and 8.51 (1H, d, $J$ 2 Hz). In each case, which isomer is it? The bonds sticking into the centre of the ring can be to any carbon atom.

**Purpose of the problem**

First steps in using coupling to decide structure.

**Suggested solution**

The coupling constants in the first spectrum are all too small to be between hydrogens on neighbouring carbon atoms, and there must be symmetry in the molecule. There is only one structure that answers these criteria: 3,5-dimethoxybenzoic acid.
The second compound has one coupling of 10 Hz, and this must be between protons on neighbouring carbon atoms. The other coupling is 2 Hz and this is too small to be anything but meta coupling. There are two structures that might be right. In fact the first one is correct and you might have worked this out from the very large chemical shift—almost in the aldehyde region—of the isolated proton with only a 2 Hz coupling. This proton is on an alkene carbon bonded to oxygen in the first structure, but on a simple alkene carbon in the second.
PROBLEM 4
Assign the NMR spectra of this compound and justify your assignments. ‘Assign’ means ‘say which signal belongs to which atom’.

Purpose of the problem
Practice in the interpretation of real NMR spectra – this is harder than if the spectra have already been analysed and reported as a list of peaks.

Suggested solution
There is no coupling in this proton NMR spectrum which makes it much easier, but you should measure the chemical shifts and estimate the number of protons in each signal from the integration. Here we have: $\delta_H ($ppm$) 1.4$
(6H), 1.8 (3H), 2.9 (2H) and 5.6 (1H). The peak at 7.5 is CHCl₃ impurity in the CDCl₃ solvent. This is enough to assign the spectrum but we should check that the chemical shifts are right and they are.

The carbon spectrum is more familiar to you from chapter 3 and you will remember that integration means little here. There are three peaks in the 0–50 ppm region corresponding to the methyl group on the alkene, the CH₂ group and the pair of methyls on the same carbon atom. The 1:1:1 triplet at 77 ppm is the solvent CDCl₃. The other signal in the 50–100 ppm region must be the carbon next to oxygen in the Me₂C group. The two signals in the 100–150 ppm region are the two carbons of the alkene and the very small peak at 150 ppm is the carbonyl group. No further assignment is necessary.

PROBLEM 5

Assign the ¹H NMR spectra of these compounds and explain the multiplicity of the signals

Purpose of the problem

First serious practice in correlating splitting patterns and chemical shift.

Suggested solution

Redrawing the molecules with all the hydrogens showing probably helps at this stage, though you will not do this for long. The spectrum of 1-nitrobutane can be assigned by integration and splitting pattern without even looking at the chemical shifts! Just counting the number of neighbours
and adding one gives the multiplicity and leads to the assignment. Alternatively you could inspect the chemical shifts which get smaller the further the protons are from the nitro group. Everything fits.

The next compound has an isopropyl group, typically a 6H doublet at about δ 1 ppm and a 1H septuplet with a larger chemical shift. Assigning the two triplets for the two CH₂ groups in the ring is not so easy as they are very similar. It doesn’t really matter which is which as this uncertainty does not affect our identification of the compound.

The aromatic ketone happens to have all five aromatic protons overlapping so they cannot be sorted out. This is not unusual and a signal in the 6.5–8 region described as ‘5H, m’ usually means a monosubstituted benzene ring. The side chain is straightforward with the CH₂ group next to the ketone having the largest shift. All the coupling constants happen to be the same (7 Hz) as is usual in an open-chain compound.
PROBLEM 6

The reaction below was expected to give the product A and did indeed give a compound with the correct molecular formula by its mass spectrum. However, the NMR spectrum of this product was:

\[ \delta_H \text{ (ppm)}: 1.27 \text{ (6H, s)}, 1.70 \text{ (4H, m)}, 2.88 \text{ (2H, m)}, 5.4–6.1 \text{ (2H, broad s, exchanges with D}_2\text{O)} \text{ and 7.0–7.5 (3H, m).} \]

Though the detail is missing from this spectrum, how can you already tell that this is not the expected product?

Purpose of the problem

To show that it is helpful to predict the NMR spectrum of an expected product provided that the structure is rejected if the NMR is 'wrong'.

Suggested solution

The spectrum is all wrong. There are only three aromatic Hs instead of the four expected. There are two exchanging hydrogens, presumably in NH$_2$ and not the one expected. The only thing that is expected is the chain of three CH$_2$ groups. If you managed to work out the product that was actually formed, you should be very pleased.

Now you know the structure of the product, you should be able to assign the spectrum and confirm the result.
PROBLEM 7

Assign the 400 MHz $^1$H NMR spectrum of this enynone as far as possible, justifying both chemical shifts and coupling patterns.

Purpose of the problem

Practice at interpretation of more complicated $^1$H NMR spectra.

Suggested solution

First measure the spectrum and list the data. The expansions make it easier to see the coupling but even so we are going to have to call the signal at 5.6 ppm a multiplet. For the rest of the signals you should have measured the $J$ values. Coupling is measured in Hz and at 400 MHz each chemical shift unit of 1 ppm is 400 Hz, so each subunit of 0.1 ppm is 40 Hz.

</table>
That gives us three protons in the alkene region, five CH₂ groups and one solitary proton which must be on the alkyne. In the alkene region, the multiplet must be H² which couples to the the CH₂ at C3 and the other two alkene Hs. On C1, H₁a has a large trans coupling (16 Hz) to H² while H₁b has a smaller cis coupling (10 Hz). The coupling between H₁a and H₁b is very small.

Of the five CH₂ groups, the quintet at small chemical shift must be C7. Those at C4, C6, and C8 have two neighbours and are basically triplets, but that at C3 couples to three protons and must be the quartet at 2.32 ppm.

**PROBLEM 8**
A nitration product (C₈H₁₁N₃O₂) of this pyridine has been isolated which has a nitro group somewhere in the molecule. From the spectrum deduce where the nitro group is and give a full analysis of the spectrum.

**Purpose of the problem**
Practice at working out the structure of a reaction product.
Suggested solution

The nitro group might go on the pyridine ring or on the aliphatic side chain or even, perhaps, on the nitrogen atom. Checking the integral shows that it must have gone on the pyridine: the propyl side chain is still there (CH₃ triplet, CH₂ quintet, and a CH₂ triplet with a large chemical shift). The NH proton is still there at 4.0 ppm. But there are now only three protons on the pyridine ring (at 6.7, 8.3, and 8.8 ppm).

There are four possible structures. The most significant feature of the aromatic ring is the proton at very large chemical shift (8.8) with only very small coupling. Protons next to nitrogen in pyridine rings have very large chemical shifts so this rules out all the structures except the second.

The nitro group also increases the shifts of neighbouring protons and so we can assign the spectrum. The rather high field of the proton on the pyridine ring at 6.6 ppm is explained by the electron-donating effect of the amino group.
PROBLEM 9
Interpret this $^1$H NMR spectrum.

Purpose of the problem
Further correlation of chemical shift and coupling with interpretation of longer-range coupling.

Suggested solution
The ethyl group is easy to find—a typical 3H triplet at 1.2 ppm and a 2H quartet at 4.3 ppm. The large shift of the CH$_2$ group tells us it is next to O. The methyl group is also easy—a 3H singlet at 2.3 ppm, typical of a methyl group on an alkene. At the other end of the spectrum, the broad singlet at 12.5 ppm can be only the OH or the NH; the other is at 5.4 ppm. That leaves the three signals in the aromatic region. You may not be able to see clearly the couplings, but they are: $\delta_H$ (ppm) 7.2 (1H, dd, $J$ 9 Hz), 7.5 (1H, d, $J$ 9 Hz), and 8.4 (1H, d, $J$ 2 Hz). The larger coupling is typical ortho and the small coupling typically meta so we can assign the whole spectrum.
PROBLEM 10

Suggest structures for the products of these reactions, interpreting the spectroscopic data. Most of the reactions will be new to you, and you should aim to solve the structures from the data, not by guessing what might happen.

**A.** C_{10}H_{14}O

\[ \text{\(v_{\text{max}}\) (cm\(^{-1}\)} \text{ C–H and fingerprint only}} \]

\[ \delta_{\text{C}} \text{ (ppm) 153, 141, 127, 115, 59, 33, 24} \]

\[ \delta_{\text{H}} \text{ (ppm) 1.21 (6H, d, J 7 Hz), 2.83 (1H, septuplet, J 7 Hz), 3.72 (3H, s), 6.74 (2H, d, J 9 Hz) and 7.18 (2H, d, J 9 Hz)} \]

**B.** C_{8}H_{14}O_{3}

\[ \text{\(v_{\text{max}}\) (cm\(^{-1}\)} 1745, 1730} \]

\[ \delta_{\text{C}} \text{ (ppm) 202, 176, 62, 48, 34, 22, 15} \]

\[ \delta_{\text{H}} \text{ (ppm) 1.21 (6H, s), 1.8 (2H, t, J 7 Hz), 2.24 (2H, t, J 7 Hz), 4.3 (3H, s) and 10.01 (1H, s)} \]

**C.** C_{14}H_{15}NO_{2}

\[ \text{\(v_{\text{max}}\) (cm\(^{-1}\)} 1730} \]

\[ \delta_{\text{C}} \text{ (ppm) 191, 164, 132, 130, 115, 64, 41, 29} \]

\[ \delta_{\text{H}} \text{ (ppm) 2.32 (6H, s), 3.05 (2H, t, J 6 Hz), 4.20 (2H, t, J 6 Hz), 6.97 (2H, d, J 7 Hz), 7.82 (2H, d, J 7 Hz) and 9.97 (1H, s)} \]

**Purpose of the problem**

Practice at determining the structures of reaction products of moderate complexity. This is a very common pastime of real chemists!

**Suggested solution**

Compound A contains the two reagents combined with the loss of HBr. The four Hs at 6.4 and 7.18 suggest the other reagent is attached to the benzene ring. The OMe group is still there (3H singlet at 3.72 ppm) and the new signals are a coupled 6H doublet and 1H septuplet—an isopropyl group. The compound is one of three isomers.
The two 2H doublets coupled with $J = 9$ Hz show that the product has symmetry and only the para isomer will fit, as both the ortho and meta compounds have four different protons. We have used the proton NMR alone but we could have mentioned that there are no functional groups other than the ether and that the four aromatic signals in the $^{13}$C NMR reflect the symmetry of the product.

Compound B combines the two reagents with the loss of Me$_3$Si and the gain of H. Both the IR and the $^{13}$C NMR show the appearance of a second carbonyl group—the ester (1745 cm$^{-1}$ and 176 ppm) has been joined by an aldehyde or ketone (1730 cm$^{-1}$ and 202 ppm). The proton NMR shows it is an aldehyde (10.01, 1H, s). There is also a CMe$_2$ group but it is no longer part of an alkene (proton and carbon NMR show that the alkene has gone). The OMe of the ester has survived. Finally, and very helpfully, there are two open chain CH$_2$ groups linked together (the two triplets with $J = 7$ Hz). One of them (2.24 ppm) has to be next to something and that can only be a carbonyl group as there is nothing else. So we have:

Though saying what 'ought to happen' is not always helpful, it obviously makes much more sense to consider first a solution in which the ester group stays where it is, on a chain of two carbon atoms, than one in which it moves mysteriously to the other end of the molecule. We prefer the first of these two possibilities:
Real evidence comes from the lack of coupling of the aldehyde proton which would surely be a triplet in the second structure. The first structure is indeed correct.

Adding up the atoms for compound C reveals that the two reagents have joined together with the loss of HF. The 1,4-disubstituted benzene ring is still there (same pattern as compound A) as is the aldehyde (1730 cm⁻¹, 191 ppm and 9.97 ppm). The NMe₂ group and the CH₂–CH₂ chain from the other reagent have also survived. It looks as though the fluoride has been displaced by the oxygen of the alcohol and this is indeed what has happened.
Suggested solutions for Chapter 14

PROBLEM 1
Are these molecules chiral? Draw diagrams to justify your answer.

![Molecules](image)

**Purpose of the problem**
Reinforcement of the very important criterion for chirality. Make sure you understand the answer.

**Suggested solution**
Only one thing matters: does the molecule have a plane of symmetry? We need to redraw some of them to see if they do. On no account look for chiral centres or carbon atoms with four different groups or anything else. *Just look for a plane of symmetry.* If the molecule has one, it isn’t chiral. The first compound has been drawn with carboxylic acids represented in two different ways. The two CO₂H groups are in fact the same and the molecule has a plane of symmetry (shown by the dashed lines). It isn’t chiral.

![Molecules](image)

The second compound is chiral but if you got this wrong don’t be dismayed. Making a model would help but there are only two plausible candidate
planes of symmetry: the ring itself, in the plane of the page, and a plane at right angles to the ring. The molecule redrawn below with the tetrahedral centre displayed shows that the plane of the page isn’t a plane of symmetry as the CO₂H is on one side and the H on the other, and neither is the plane perpendicular to the ring, as Ph is on one side and H on the other. No plane of symmetry: molecule is chiral.

The third compound is not chiral because of its high symmetry. All the CH₂ groups are identical so the alcohol can be attached to any of them. The plane of symmetry (shown by the dotted lines) may be easier to see after redrawing, and will certainly be much easier to see if you make a model.

The fourth compound needs only the slightest redrawing to make it very clear that it is not chiral. The dashed line shows the plane of symmetry at right angles to the paper.

The final acetal (which is a spiro compound) is drawn flat but the central carbon atom must in fact be tetrahedral so that the two rings are orthogonal. By drawing first one and then the other ring in the plane of the page it is easy to see that neither ring is a plane of symmetry for the other because of the oxygen atoms.
PROBLEM 2
If a solution of a compound has an optical rotation of +12, how could you tell if this was actually +12 or really –348 or +372?

Purpose of the problem
Revision of the meaning of optical rotation and what it depends on.

Suggested solution
Check the equation (p. 310 of the textbook) that states that rotation depends on three things: the rotating power of the molecule, the length of the cell used in the polarimeter, and the concentration of the solution. We can't change the first, we may be able to change the second, but the third is easiest to change. If we halve the concentration, the rotation will change to +6, –174, or +186. That is not quite good enough as the last two figures are the same, but any other change of concentration will distinguish them.

PROBLEM 3
Cinderella's glass slipper was undoubtedly a chiral object. But would it have rotated the plane of polarized light?

Purpose of the problem
Revision of cause of rotation and optical activity.

Suggested solution
No. The macroscopic shape of an object is irrelevant. Only the molecular structure matters as light interacts with electrons in the molecules. Glass is not chiral (it is usually made up of inorganic borosilicates). Only if the slipper had been made of single enantiomers of a transparent substance would it have rotated the plane of polarized light. The molecules of Cinderella's left foot are the same as those in her right foot, despite both feet being macroscopically enantiomeric.
**PROBLEM 4**

Discuss the stereochemistry of these compounds. *Hint:* this means saying how many diastereoisomers there are, drawing clear diagrams of each, and stating whether they are chiral or not.

---

**Purpose of the problem**

Making sure you can handle this important approach to the stereochemistry of molecules.

**Suggested solution**

Just follow the hint in the question! Diastereoisomers are different compounds so they must be distinguished first. Then it is easy to say if each diastereoisomer is chiral or not. The first two are simple:

---

The third structure could exist as two diastereoisomers. The one with the *cis* ring junction has a plane of symmetry and is not chiral. The one with the *trans* ring junction has no plane of symmetry and is chiral (it has $C_2$ symmetry). Only one enantiomer is shown here.

---

The last compound is most complicated as it has no symmetry at all. We can have two diastereoisomers and neither has a plane of symmetry. Both the *cis* compound and the *trans* compound can exist as two enantiomers.
PROBLEM 5
In each case state, with explanations, whether the products of these reactions are chiral and/or enantiomerically pure.

Purpose of the problem
Combining mechanism and stereochemical analysis for the first time.

Suggested solution
We need a mechanism for each reaction, a stereochemical description for each starting material (achiral, chiral? enantiomerically enriched?) and an analysis of what happens to the stereochemistry in each reaction. Don’t forget: you can’t get single enantiomers out of nothing—if everything that goes into a reaction is racemic or achiral, so is the product.

In the first reaction the starting material is achiral as the two CH$_2$OH side chains are identical. The product is chiral as it has no plane of symmetry but it cannot be one enantiomer as that would require one of the CH$_2$OH side chains to cyclize rather than the other. It must be racemic.
The starting material for the second reaction is planar and achiral. If the reagent had been sodium borohydride, the product would be chiral but racemic. But an enzyme, because it is made up of enantiomerically pure components (amino acids), can deliver hydride to one side of the ketone only. We expect the product to be enantiomerically enriched.

In the third reaction, the starting material is one enantiomer of a chiral compound. So we need to ask what happens to the chiral centre during the reaction. The answer is nothing as the reaction takes place between the amine and the carboxylic acid. The product is a single enantiomer too.

The final problem is a bit of a trick. The starting material is chiral, but racemic while the product is achiral as the two CH₂CH₂OH side chains are identical so there can be a plane of symmetry between them. The mechanism doesn’t really matter but we might as well draw it.

**Problem 6**

This compound racemizes in base. Why is that?

**Purpose of the problem**

To draw your attention to the dangers in working with nearly symmetrical molecules and revision of ester exchange (textbook p. 209).
Suggested solution

Ester exchange in base goes in this case through a symmetrical (achiral) tetrahedral intermediate with a plane of symmetry. Loss of the right hand leaving group gives one enantiomer of the ester and loss of the left hand leaving group gives the other.

PROBLEM 7

Assign a configuration (R or S) to each of these compounds.

Purpose of the problem

Nomenclature may be the least important of the organic chemist’s necessary skills, but giving R or S designation to simple compounds is an essential skill. These three examples check your basic knowledge of the rules.

Suggested solution

Carrying out the procedure given in the chapter (pp. 308–9 of the textbook) we prioritize the substituents 1–4 and deduce the configuration. In all these cases ‘4’ is H and goes at the back when we work out the configuration. The first compound is Pirkle’s chiral solvating agent, used to check the purity of enantiomerically enriched samples. The next is the amino acid cysteine and, despite being the natural enantiomer, is R because S ranks higher than O (all other natural amino acids are S). The third is natural citronellol having three carbon atoms on the chiral centre. They are easily ranked by the next atom along the chain or the atom beyond that if necessary.
PROBLEM 8

Just for fun, you might try and work out just how many diastereoisomers there are of inositol and how many of them are chiral.

Purpose of the problem

Fun, it says! There is a more serious purpose in that the relationship between symmetry and stereochemistry is interesting, and, for this human brain chemical, important to understand.

Suggested solution

If we start with all the OH groups on one side and gradually move them over, we should get the answer. If you got too many diastereoisomers, check that some are not the same as others. There are eight diastereoisomers altogether and, remarkably, only one is chiral. All the others have at least one plane of symmetry (shown as dotted lines).
Solutions for Chapter 14 – Stereochemistry

- All OHs up: achiral (many planes)
- Four OHs up: achiral
- Five OHs up: three OHs up
- Three OHs up: achiral
- Three OHs up: achiral (many planes)
This page intentionally left blank
Suggested solutions for Chapter 15

**PROBLEM 1**
Suggest mechanisms for the following reactions, commenting on your choice of $S_N1$ or $S_N2$.

Purpose of the problem
Simple example of the two important mechanisms of chapter 15: $S_N1$ and $S_N2$.

Suggested solution
NaOH ($pK_a$ of water about 16) removes the proton from PhSH ($pK_a$ about 7) rapidly as this is a proton transfer between electronegative atoms. Clearly the methyl group must be transferred from O to S and this must be an $S_N2$ reaction.

The first reagent in the second reaction resembles the reagent in the first reaction but it is the free sulfonic acid and not the ester. The ether product must come from the displacement of OH from one molecule of $t$-BuOH by the OH group of the other and this can only be an $S_N1$ reaction. The OH group leaves as H$_2$O after being protonated by the sulfonic acid.
PROBLEM 2

Arrange the following in order of reactivity towards the nucleophile sodium azide. Give a brief comment for each compound to explain what factor influences its place in the reactivity scale.

Purpose of the problem

Revision of the factors affecting reactivity in a series of S$_{N2}$-reactive molecules.

Suggested solution

None of these compounds has structural features necessary to promote S$_{N1}$ (not even the third: notice that the bromine is attached to a primary carbon, even though there is a tert-butyl group in the molecule), so we need to think about S$_{N2}$ reactivity only. In general, steric hindrance slows down S$_{N2}$ reactions, so we can start by saying that methyl bromide > n-butyl bromide > cyclohexyl bromide. But how do the other two fit into the scale? An adjacent carbonyl group accelerates S$_{N2}$ reactions enormously, so the ketone will react even faster than methyl bromide. On the other hand, a bulky tert-butyl group adjacent to a reaction centre leads to very slow substitution, so this compound (‘neopentyl bromide’) goes at the bottom of the scale.
**PROBLEM 3**

Draw mechanisms for these reactions, explaining why these particular products are formed.

Purpose of the problem

How to choose between SN1 and SN2 when the choice is more subtle.

**Suggested solution**

The first compound has two leaving groups—both secondary chlorides. The one that leaves is next to oxygen so that suggests SN1 (the oxygen lone pair can stabilize the cation) as does the reagent: surely MeO⁻ would be used for SN2.

The second compound has only one leaving group and that must be protonated before it can leave. It has two possible sites for attack by the nucleophile (Cl⁻), one primary and one secondary. As the primary is chosen, this must be SN2.
PROBLEM 4
Suggest how to carry out the following transformations.

Purpose of the problem
Choosing reagents for substitution reactions of alcohols.

Suggested solution
The first compound can react by $S_N 1$, so we have an opportunity to use an excellent reaction: just treating the alcohol with HBr will give the bromide. The second compound is primary, so we have to make it react by $S_N 2$. But we can’t simply try to get $\text{OH}^-$ to leave (hydroxide is never a leaving group!). We have to convert the alcohol into a better leaving group, and we can do this just by treating with $\text{PCl}_3$ (or we could make a sulfonate leaving group and displace with chloride).

The final example must be an $S_N 2$ reaction because it involves an inversion of configuration. Again, hydroxide cannot be a leaving group, so we have to make the alcohol into a tosylate first. We could then use hydroxide as a nucleophile, but to avoid competing elimination reactions the next step is usually done in two stages using acetate as the nucleophile and then hydrolysing to the alcohol.
PROBLEM 5
Draw mechanisms for these reactions and give the stereochemistry of the product.

Purpose of the problem
Drawing mechanisms for two types of nucleophilic substitution in the same sequence to make a β-lactam antibiotic.

Suggested solution
We need an S_N2 reaction at a primary carbon and a nucleophilic substitution at the carbonyl group with the amino group as the nucleophile in both cases. The carbonyl group reaction probably happens first. Don’t worry if you didn’t deprotonate the amide before the S_N2 reaction. The stereochemistry is the same as that of the starting material (CO_2Et up as drawn) as no change has occurred at the chiral centre.
**PROBLEM 6**

Suggest a mechanism for this reaction. You will find it helpful first of all to draw good diagrams of reagents and products.

\[ \text{t-BuNMe}_2 + (\text{MeCO})_2\text{O} \rightarrow \text{Me}_2\text{NCOMe} + \text{t-BuO}_2\text{CMe} \]

**Purpose of the problem**

Revision of chapter 2 and practice at drawing mechanisms of unusual reactions.

**Suggested solution**

First draw good diagrams of the molecules as the question suggests.

With an unfamiliar reaction, it is best to identify the nucleophile and the electrophile and see what happens when we unite them. The nitrogen atom is obviously the nucleophile and one of the carbonyl groups must be the electrophile.

We must lose a t-butyl group from this intermediate to give one of the products and unite it with the acetate ion to give the other. This must be an \(S_N1\) rather than an \(S_N2\) at a t-butyl group.
**PROBLEM 7**

Predict the stereochemistry of these products. Are they diastereoisomers, enantiomers, racemic or what?

![Reaction Scheme](image)

**Purpose of the problem**

Revision of stereochemistry from chapter 14 and practice at applying it to substitution reactions.

**Suggested solution**

The starting material in the first reaction has a plane of symmetry so it is achiral: the stereochemistry shows only which diastereoisomer we have. Attack by the amine nucleophile at either end of the epoxide (the two ends are the same) must take place from underneath for inversion to occur. The product is a single diastereoisomer but cannot, of course, be a single enantiomer so it doesn’t matter which enantiomer you have drawn. The stereochemistry of the Ph group cannot change—it is just a spectator.

![Intermediate Scheme](image)

The starting material for the second reaction is also achiral as it too has a plane of symmetry. The stereochemistry merely shows that the two OTs groups are on the same side of the molecule as drawn. Displacement with sulfur will occur with inversion and it is wise to redraw the intermediate before the cyclization. This ‘inverts’ the chiral centre so that we can see that the stereochemistry of the product has the methyl groups *cis*. There are various ways to draw this.
PROBLEM 8
What are the mechanisms of these reactions, and what is the role of the ZnCl₂ in the first step and the NaI in the second?

Purpose of the problem
Exploration of two different kinds of catalysis in substitution reactions.

Suggested solution
The ZnCl₂ acts as a Lewis acid and can be used either to remove chloride from MeCOCl or to complex with its carbonyl oxygen atom, in either case making it a better electrophile so that it can react with the unreactive oxygen atom of the cyclic ether. Ring cleavage by chloride follows.

The second reaction is an S_N2 displacement of a reasonable leaving group (chloride) by a rather weak nucleophile (acetate). The reaction is very slow unless catalysed by iodide ion—a better nucleophile than acetate and a better leaving group than chloride.
PROBLEM 9
Describe the stereochemistry of the products of these reactions.

Purpose of the problem
Nucleophilic substitution and stereochemistry, with a few extra twists.

Suggested solution
The ester in the first example is removed by reduction leaving an oxyanion that cyclizes by intramolecular $S_N2$ reaction with inversion giving one diastereoisomer (cis) of the product. The product is achiral.

The second case involves an intramolecular $S_N2$ reaction on one end of the epoxide. The reaction occurs stereospecifically with inversion and so one enantiomer of one diastereoisomer of the product is formed. Some redrawing is needed and we have left the epoxide in its original position to avoid mistakes.

You can read more about this in B. S. Furniss et al., Vogel's textbook of organic chemistry (5th edn), Longmans, Harlow, 1989, p. 492.
**PROBLEM 10**

State, with reasons, whether these reactions will be $S_N1$ or $S_N2$.

**Purpose of the problem**

Taxing examples of the choice between our two main mechanisms. The last two differ only in reaction conditions.

**Suggested solution**

The first reaction offers a choice between an $S_N2$ reaction at a tertiary carbon or an $S_N1$ reaction next to a carbonyl group. Neither looks very good but experiments have shown that these reactions go with inversion of configuration and they are about the only examples of $S_N2$ reactions at tertiary carbon. They work because the $p$ orbital in the transition state is stabilized by conjugation with the carbonyl group: $S_N2$ reactions adjacent to C=O groups are usually fast.

The moment that you see acetal-like compounds in the second example, you should suspect $S_N1$ with oxonium ion intermediates. In fact the compounds are orthoesters but this makes no difference to the mechanism. If you are not sure of this sort of chemistry, have a look at chapter 11. The OH group displaces the OMe group by an acid-catalysed $S_N1$ reaction.
The last two examples add the same group (OPr) to the same compound (an epoxide) to give different products. We can tell that the first is $S_N1$ as PrOH adds to the more substituted (tertiary and benzylic) position. Inversion occurs because the nucleophile prefers to add to the less hindered face opposite the OH group. If you said that it is an $S_N2$ reaction at a benzylic centre with a loose cationic transition state, you may well be right.

The second is easier as the more reactive anion adds to the less hindered centre with inversion and this must be $S_N2$. 
**PROBLEM 11**

The pharmaceutical company Pfizer made the antidepressant reboxetine by the following sequence of reactions. Suggest a reagent for each step, commenting on aspects of stereochemistry or reactivity.

Purpose of the problem

Thinking about substitution reactions in a real synthesis. It might look challenging, but each step uses a reaction you have already met.

Suggested solution

The first step is the attack of a nucleophile on an epoxide. It’s an S\textsubscript{N}2 reaction, because it goes with inversion of configuration, and we need a phenol as the nucleophile. To make the phenol more reactive, we probably want to deprotonate it to make the phenoxide, and NaOH will do this. Why does this end of the epoxide react? Well, it is next to a phenyl ring, and benzylic S\textsubscript{N}2 reactions are faster than reactions at ‘normal’ secondary carbons. Next the end hydroxyl group is made into a leaving group (a ‘mesylate’), for which we need methanesulfonyl chloride (mesyl chloride) and triethylamine. The primary hydroxyl group must react faster than the secondary one because it is less hindered.
The next stage is an intramolecular substitution leading to formation of a new epoxide. The hydroxyl group is the nucleophile and the methanesulfonate (MsO−) group the leaving group. We need base to do this, and sodium hydroxide is a good choice. Now the epoxide can be opened (at its more reactive, less hindered end) with a nitrogen nucleophile: ammonia might be a possible choice, but often better is azide, followed by reduction by hydrogenation or LiAlH₄. The amine product is converted into an amide, so we need an acid chloride and base.

Another intramolecular substitution follows, this time with an alcohol nucleophile displacing a chloride leaving group to make a new ring. A strong base will make the alcohol nucleophilic by deprotonating it to form the epoxide, and KOt-Bu works here (though if you just suggested ‘base’ that is fine: only experimentation will show which works best). Finally, the amide is reduced to an amine, for which we need LiAlH₄.
Suggested solutions for Chapter 16

PROBLEM 1
Identify the chair or boat rings in the following structures and say why this particular structure is adopted.

Purpose of the problem
Exploration of simple examples of chair and boat forms.

Suggested solution
The first three are relatively simple. The first has a chair with all substituents equatorial. The second is forced to have a boat as no chair is possible but the third has a normal chair with a 1,3-diaxial bridge.

Two have nothing but boats as chairs are impossible. One has three boats and the other just the one as there is only one six-membered ring.

The remaining molecule is adamantane – a tiny fragment of a diamond. It is more symmetrical than a paper diagram can show but a model reveals a beautifully symmetrical structure. All the rings are chairs, though some don’t look very chair-like in our diagrams.
**PROBLEM 2**

Draw clear conformational drawings of these molecules, labelling each substituent as axial or equatorial.

Purpose of the problem

Simple practice at drawing chair cyclohexanes with axial and equatorial substituents.

Suggested solution

Your drawings may look different from ours but make sure the rings have parallel sides and don’t ‘climb upstairs’ (pp. 371–372 in the textbook). Make sure that the axial bonds are vertical and the equatorial bonds parallel to the next ring bond but one. The easiest strategy with this question is to draw a ring accurately, and then to add the substituents. The first molecule is simple: there is only one substituent, a large bromine atom, so it goes equatorial. In the second molecule, the two substituents have to be on opposite sides of the ring: this allows them both to be equatorial, which of course they prefer. The last two molecules are dominated by the large t-butyl group which insists on being equatorial. Once you have put an equatorial t-butyl group on the last molecule you find that there is no choice but to put the Me and OH groups axial.
**PROBLEM 3**

Would the substituents in these molecules be axial, equatorial, or a mixture between the two?

![Molecules](image)

**Purpose of the problem**

Simple practice at drawing chair cyclohexanes and deciding whether the substituents are axial or equatorial. Remember to decide by drawing and not by trying to remember rules.

**Suggested solution**

All three molecules have a free choice as the substituents aren’t large and are about the same size. Note that all three molecules have their substituents ‘trans’ but in two they are both equatorial and in one they are axial/equatorial.

![Molecules](image)

**PROBLEM 4**

Which of these two compounds would form an epoxide on treatment with base?

![Molecules](image)

**Purpose of the problem**

Exploration of the relationship between conformation and mechanism.
Suggested solution

The mechanism is easy (intramolecular S$_{N}$2) and the conformation of a trans decalin is fixed so we can start with the conformational drawings.

![Conformational drawings]

The first compound can get the necessary ‘attack from the back’ angle of 180° between the nucleophile (O$^-$) and the leaving group (Br) for the intramolecular reaction. But this is impossible for the second compound.

PROBLEM 5

It is more difficult to form an acetal from the first of these compounds than from the second. Why is this?

![Acetal formation]

Purpose of the problem

Exploration of the effect of conformation on equilibria in thermodynamically controlled reactions.

Suggested solution

The mechanism of the reaction is normal acetal formation and is irrelevant to the question as acetal formation is thermodynamically controlled: it is only the structure and stability of the product that matters. We need to look at the conformations of the molecules to find out which is the more stable.
Axial groups 1,3-related to the ketone are not important as there is no axial group on the ketone. But one of the oxygen atoms in the acetal must be axial and there is now a bad 1,3-diaxial interaction with the methyl group in the first but not in the second acetal. Though the first ketone is slightly less stable than the second, the first acetal is markedly less stable than the second.

**PROBLEM 6**

Hydrolysis of the tricyclic bromide below in water gives an alcohol. What is the conformation of the bromide and what will be the stereochemistry of the alcohol?

Purpose of the problem

Exploring the conformation of a tricyclic system and discovering that conformation can control stereochemistry even of $S_{N}1$ reactions. (Yes, you do need to work out for yourself that this is an $S_{N}1$ reaction.)

Suggested solution

The mechanism of the reaction is obviously $S_{N}1$ as it is a tertiary bromide and the reagent is water, a weak nucleophile. The water molecule can approach from either side of the planar cation intermediate. There is a unique conformation of the starting material with all three rings in chair conformations and this will be much preferred in the product. The reaction goes with retention as it is under thermodynamic control.
PROBLEM 7
Treatment of the triol below with benzaldehyde in acid solution produces one diastereoisomer of an acetal but none of the alternative acetal. Why is one acetal preferred? (Hint: what controls acetal formation?) What is the stereochemistry of the undefined centre in the acetal that is formed?

Purpose of the problem
Exploration of conformational control in acetal formation.

Suggested solution
Acetal formation is thermodynamically controlled (p. 226 in the textbook) so we need look only for the most stable possible product. The one that is not formed is a cis-decalin as that would be significantly less stable than the trans-decalin that is formed. The phenyl group prefers to adopt an equatorial position and that will decide the stereochemistry as all the acetals are in equilibrium. The remaining OH has to be axial because of its configuration in the starting material.
**PROBLEM 8**
The compound below is the painkiller tramadol. Draw the most likely conformation of its six-membered ring.

**Purpose of the problem**
Conformation of a drug molecule.

**Suggested solution**
As before, just draw a chair, then add substituents. Here we have one carbon with two substituents, but the large aryl ring will prefer to be equatorial. This also allows the amine substituent to be equatorial.
This page intentionally left blank
Suggested solutions for Chapter 17

**PROBLEM 1**
Draw mechanisms for these elimination reactions.

Purpose of the problem
Exercise in drawing simple eliminations.

Suggested solution
These are both E2 reactions as the leaving groups are on primary carbons. In fact both of these reaction are in the textbook (pp. 387 and 391 of the textbook).

The structure of the amidine base, DBU, and why it is used in elimination reactions is discussed in the textbook on p. 387.
PROBLEM 2
Give a mechanism for the elimination reaction in the formation of tamoxifen, a breast cancer drug, and comment on the roughly 50:50 mixture of geometrical isomers (cis- and trans-alkenes)

Purpose of the problem
Thinking about the stereochemical consequences of E1.

Suggested solution
The tertiary alcohol leaving group, the acid catalyst, and the 50:50 mixture all suggest E1 rather than E2. There is only one proton that can be lost and, as there is very little difference between the isomeric alkenes, equilibration probably gives the 50:50 mixture.

The fact that equilibration of the products of E1 elimination gives the most stable possible alkene is discussed in the textbook on p. 394.
PROBLEM 3
Suggest mechanisms for these eliminations. Why does the first give a mixture and the second a single product?

\[
\begin{align*}
\text{OH} & \quad \text{H}_3\text{PO}_4 \quad \text{heat} \\
\text{OH} & \quad \text{OH} \\
\text{OH} & \quad \text{OH} \\
\end{align*}
\]

Heat \quad \text{64\% yield, 4:1 ratio}

Heat \quad 48\% \text{HBr}

Purpose of the problem
Regioselectivity of eliminations.

Suggested solution
Whether the first reaction is E1 or E2, there are two sets of hydrogen atoms that could be lost in the elimination. The conditions suggest E1 and the major product may be so because of equilibration.

The second reaction produces a more stable tertiary cation from which any of six protons could be lost, but all give the same product. Repetition gives the diene.

The fact that equilibration of the products of E1 elimination gives the most stable possible alkene is discussed in the textbook on p. 394.
PROBLEM 4
Explain the position of the alkene in the products of these reactions. The starting materials are enantiomerically pure. Are the products also enantiomerically pure?

**Purpose of the problem**
Examples of E1cB in the context of absolute stereochemistry.

**Suggested solution**
The first reaction is an E1cB elimination of a β-hydroxy-ketone. The product is still chiral although it has lost one stereogenic centre. The other (quaternary) centre is not affected by the reaction so the product is enantiomerically pure.

E1cB reactions are on p. 399 in the textbook

The second example already has an electron-rich alkene (an enol ether) present in the starting material so this is more of an E1 than an E1cB mechanism. The intermediate is a hemiacetal that hydrolyses to a ketone (p. 224 in the textbook). The product has two chiral centres unaffected by the reaction and is still chiral so it is also enantiomerically pure.
**PROBLEM 5**

Explain the stereochemistry of the alkenes in the products of these reactions.

**Purpose of the problem**

Display your skill in a deceptive example of control of alkene geometry by elimination.

**Suggested solution**

The first reaction is stereospecific cis addition of hydrogen to an alkyne to give the cis-alkene. The intermediate is therefore a cis,cis-diene and it may seem remarkable that it should become a trans,trans-diene on elimination. However, when we draw the mechanism for the elimination, we see that there need be no relationship between the stereochemistry of the intermediate and the product as this is an E1 reaction and the cationic intermediate can rotate into the most stable shape before conversion to the aldehyde.

The hydrogenation of alkynes to give cis alkenes is described on p. 537 of the textbook.
PROBLEM 6
Suggest a mechanism for this reaction and explain why the product is so stable.

Purpose of the problem
Exploring what might happen on the way to an elimination and explaining special stability.

Suggested solution
The obvious place to start is cyclization of the phenol onto a ketone to form a six-membered ring. The product is a hemiacetal that will surely eliminate by a combination of hemiacetal hydrolysis and the E1cB mechanism.

The final product is particularly stable as the right hand ring is aromatic. It has two alkenes and a lone pair on oxygen, making six electrons in all. If you prefer you can show the delocalization to make the ring more benzene-like.
PROBLEM 7
Comment on the position taken by the alkene in these eliminations.

Purpose of the problem
Further exploration of the site occupied by the alkene after an elimination.

Suggested solution
The first is an E1cB reaction after methylation makes the amine into a leaving group. The alkene has to go where the amine was (and in conjugation with the ketone).

The second is also E1cB and so the alkene must end up conjugated with the ketone. But this time the leaving group is on the ring so that is where the alkene goes. The stereochemistry is irrelevant as the enolate has lost one chiral centre and there is no requirement in E1cB for H and OH to be antiperiplanar.

The third is an E2 reaction so there is now a requirement for H and Br to be anti-periplanar. This means that the Br must be axial and only one hydrogen is then in the right place.
PROBLEM 8
Why is it difficult (though not impossible) for cyclohexyl bromide to undergo an E2 reaction? What conformational changes must occur during this reaction?

Purpose of the problem
Simple exploration of the relationship between conformation and mechanism.

Suggested solution
Cyclohexyl bromide prefers the chair conformation with the bromine equatorial. It cannot do an E2 reaction in this conformation as E2 requires the reacting C–H and C–Br bonds to be anti-periplanar. This can be achieved if the molecule first flips to put the C–Br bond in an unfavourable axial conformation.
PROBLEM 9

Only one of these bromides eliminates to give alkene A. Why? Neither alkene eliminates to give alkene B. Why not?

Purpose of the problem

Helping you to understand that cage molecules often have restricted opportunity for elimination.

Suggested solution

The first molecule has one H antiperiplanar to the Br atom so elimination can occur. The second has no hydrogens antiperiplanar to Br. Alkene B is a bridgehead alkene and cannot exist (see the textbook, pp. 389–390).
PROBLEM 10
Account for the contrasting results of these two reactions.

Purpose of the problem
How configuration controls mechanism, and an alternative type of elimination.

Suggested solution
The two compounds differ only in their configuration, and as they both have a tert-butyl group they have no choice about their conformation. The bromide must be the leaving group, and when you draw the molecules you find that it must also be axial. In the first case there is a proton antiperiplanar to it that can lead to a conjugated alkene. In the second case, the bond antiperiplanar to the bromine is a C–C bond, but that’s OK on this occasion because decarboxylation can take place by the mechanism shown. There is an antiperiplanar C–H bond on the other side of course, but the decarboxylation must be faster than simple E2 elimination.
Suggested solutions for Chapter 18

PROBLEM 1
A compound C_6H_5FO has a broad peak in the infrared at about 3100-3400 cm^{-1} and the following signals in its (proton decoupled) ^{13}C NMR spectrum. Suggest a structure for the compound and interpret the spectra.

δ_C (ppm) 157.4 (d, J=229 Hz), 151.2 (s), 116.3 (d, J=7.5 Hz), and 116.0 (d, J=23.2 Hz).

Purpose of the problem
A reminder that coupling may occur in ^{13}C NMR spectra too and can be useful.

Suggested solution
All the signals are in the sp^2 region and two (at >150 ppm) are of carbons attached to electronegative elements. As the formula contains C_6, a benzene ring is strongly suggested. The IR spectrum tells us that we have an OH group, so the compound is one of these three:

\[
\begin{align*}
\text{F} & \quad \text{OH} \\
\text{H} & \quad \text{F} \\
\text{H} & \quad \text{F}
\end{align*}
\]

The symmetry of the spectrum suggests the para disubstituted compound as there are only four types of carbon atom. We can assign the spectrum by noting that the very large coupling (J=229) must be a 2^J_CF and the zero coupling must be the carbon furthest from F, i.e. the para carbon. The intermediate couplings are for the other two carbons and the CF coupling diminishes with distance.
PROBLEM 2
The natural product bullatenone was isolated in the 1950s from a New Zealand myrtle and assigned the structure A. Then authentic compound A was synthesized and found not to be identical to natural bullatenone. Predict the expected $^1H$ NMR spectrum of A. Given the full spectroscopic data, not available in the 1950s, say why A is definitely wrong and suggest a better structure for bullatenone.

Spectra of isolated bullatenone:
Mass spectrum: m/z 188 (10%) (high resolution confirms C$_{12}$H$_{12}$O$_2$), 105 (20%), 102 (100%), and 77 (20%)
Infrared: 1604 and 1705 cm$^{-1}$
$^1H$ NMR: $\delta_H$ (ppm) 1.43 (6H, s), 5.82 (1H, s), 7.35 (3H, m), and 7.68 (2H, m).

Purpose of the problem
Detecting wrong structures teaches us to be alert to what the spectra are telling us rather than what we expect or want.

Suggested solution
The mass spectrum and IR are all right for A but the NMR shows at once that the structure is wrong. There is a monosubstituted benzene ring all right, but the aliphatic protons are a 6H singlet, presumably a CMe$_2$ group, and a 1H singlet in the alkene region at 5.82 ppm.

The fragments we have are Ph, carbonyl, a CMe$_2$ group, and an alkene with one proton on it. That adds up to C$_{12}$H$_{12}$O leaving only one oxygen to fit in somewhere. There must still be a ring or there would not be enough hydrogen atoms and the ring must be five-membered (just try other possibilities yourself). There are three ring systems we can choose and each can have the Ph group at either end of the alkene, making six possibilities in all.
The last four are esters (cyclic esters or lactones) and they would have a C=O frequency at 1745–1780 cm^{-1} so D–G are all wrong. The hydrogen on the alkene cannot be next to oxygen as it would have a very large chemical shift indeed whereas it is close to the ‘normal’ alkene shift of 5.25 ruling out structure C. Structure B is correct and the spectrum can be assigned. Compound B has now been synthesized and proved identical to natural bullatenone.

PROBLEM 3
Suggest structures for each of these reaction products, interpreting the spectroscopic data. You are not expected to give mechanisms for the reactions and you must resist the temptation to say what ‘ought to happen’. These are all unexpected products.

A. C_6H_{12}O_2
\n\nu_{\text{max}} (\text{cm}^{-1}) \ 1745
\n\delta_{\text{C}} (\text{ppm}) 179, 52, 39, 27
\n\delta_{\text{H}} (\text{ppm}) 1.20 (9H, s) and 3.67 (3H, s)

B. C_6H_{10}O_3
\n\nu_{\text{max}} (\text{cm}^{-1}) 1745, 1710
\n\delta_{\text{C}} (\text{ppm}) 203, 170, 62, 39, 22, 15
\n\delta_{\text{H}} (\text{ppm}) 1.28 (3H, t, J 7 Hz), 2.21 (3H, s)
3.24 (2H, s) and 4.2 (2H, q, J 7 Hz)

C. m/z 118
\n\nu_{\text{max}} (\text{cm}^{-1}) 1730
\n\delta_{\text{C}} (\text{ppm}) 202, 45, 22, 15
\n\delta_{\text{H}} (\text{ppm}) 1.12 (6H, s), 2.28 (3H, s)
and 9.8 (1H, s)

Purpose of the problem
A common situation in real life—you carry out a reaction, isolate the product, and it’s something quite different from what you were expecting. What is it?

Suggested solution

Compound A has a carbonyl group (IR) that is an acid derivative (179 ppm in the 13C NMR). The 9H singlet in the proton NMR must be a t-Bu group and the 3H singlet at 3.67 ppm must be an OMe group. Putting these four fragments together we get a structure immediately. The IR is typical for an ester (1715 + 30 = 1745 cm$^{-1}$).

![Structure A]

Compound B again has an ester (1745 cm$^{-1}$ and 170 ppm) but it also has a ketone (1710 cm$^{-1}$ and 203 ppm). The proton NMR shows an OEt group (3H triplet and 2H quartet) together with another methyl group next to something electron-withdrawing (that can only be a C=O as there isn’t anything else), and a CH$_2$ group with no coupling at 3.24 ppm. This is 2 ppm away from a ‘normal’ CH$_2$ but it can’t be next to O as we’ve used up all the O atoms already. It must be between two electron-withdrawing groups. These can only be carbonyls so this CH$_2$ is isolated between the two carbonyl groups and we have the structure.

![Structure B]

Compound C has no formula given, just a molecular ion in the mass spectrum. The most obvious formula is C$_5$H$_{10}$O$_3$ but S is 32 while O is 16 so it might be C$_5$H$_{10}$OS. We must look at the rest of the spectra for clarification. There is a carbonyl group (1730 cm$^{-1}$) that is an aldehyde or ketone (202 ppm). The proton NMR shows a CM$_2$ group (6H, s), a methyl group at 2.8 ppm that doesn’t look like an OMe (expected 3-3.5 ppm), but might be an SMe. The carbon spectrum also suggests SMe rather than OMe at 45 ppm, and one hydrogen atom at 9.8 ppm that looks like an aldehyde. We know we have these fragments:

![Fragments C]

It is not possible to construct a molecule with two extra oxygen atoms but without an OMe, and those we could propose look rather unstable, such as:
Only one compound is possible if we have an S atom—this fits the data very much better and indeed is the correct structure. It has a genuine aldehyde (not a formate ester) and SMe fits better than OMe the signal at $\delta$H 2.8 ppm and $\delta_C$ 45 ppm.

**PROBLEM 4**

Suggest structures for the products of these reactions.

**Compound A**: C$_7$H$_{12}$O$_3$; IR 1725 cm$^{-1}$; $\delta$H (ppm) 1.02 (6H, s), 1.66 (2H, t, J 7 Hz), 2.51 (2H, t, J 7 Hz), and 4.6 (2H, s).

**Compound B**: m/z 149/151 (M$^+$ ratio 1:3); IR 2250 cm$^{-1}$; $\delta$H (ppm) 2.0 (2H, quintet, J 7 Hz), 2.5 (2H, t, J 7 Hz), 2.9 (2H, t, J 7 Hz), and 4.6 (2H, s).

**Purpose of the problem**

More practice at the important skill of total structure determination.

**Suggested solution**

The starting material for A is C$_7$H$_{12}$O$_3$ and appears just to have lost an oxygen atom. As the reagent is NaBH$_4$, the chances are that two hydrogens have been added and the oxygen lost as a water molecule. The IR spectrum shows a carbonyl group and the frequency suggests an ester or a strained ketone. The NMR shows two joined CH$_2$ groups, one at 2.51 being next to a functional group, not O and so it must be C=O. There is also an unchanged CMe$_3$ group and an isolated CH$_3$ group next to oxygen at 3.9 ppm. There is only one reasonable structure.
The mass spectrum of compound B shows that it has chlorine in it, the IR shows a CN group and the proton NMR shows eight Hs. If we assume that no carbons have been lost, the most reasonable formula is C₅H₈ClNS. The compound has lost a water molecule. The NMR shows three linked CH₂ groups with triplets at the ends and a quintet in the middle. The shifts of the terminal CH₂s show that they are next to functional groups but not Cl. This means we must have a unit –SCH₂CH₂CH₂CN. All that remains is the isolated CH₂ group with a large chemical shift evidently joined to both the S and Cl. The large shift comes from 1.5 + 1 (S) + 2 (Cl) = 4.5 ppm. Again only one structure emerges.
PROBLEM 5
Two alternative structures are shown for the products of these reactions. Explain in each case how you would decide which product is actually formed. Several pieces of evidence will be required and estimated values are better than general statements.

Purpose of the problem
To get you thinking the other way round: from structure to data. What are the important pieces of evidence?

Suggested solution
There are many acceptable ways in which you could answer this question ranging from choosing just one vital statistic for each pair to analysing all the data. We'll adopt a middle way and point out several important distinctions. In the first example, one main difference is the ring size, seen mainly in the IR. Both are esters (about 1745 cm⁻¹) but we should add 30 cm⁻¹ for the five-membered ring. The functional group next to OCH₂ is also different—an OH in one case and an ester in another. There will be other differences too of course.

In the second case there are also differences in the IR C=O stretch between the aldehyde (about 1730 cm⁻¹) and the conjugated ketone (about
1680 cm\(^{-1}\)). The aldehyde proton and the number of protons next to oxygen make a clear distinction. There will also be differences in the \(^1H\) and \(^{13}C\) NMR signals of the benzene rings as one is conjugated to a C=O group and the other is not. This reaction actually gave a mixture of both compounds.

![NMR spectra of sodium fluoropyruvate in D\(_2\)O](image)

**PROBLEM 6**
The NMR spectra of sodium fluoropyruvate in D\(_2\)O are given below. Are these data compatible with the structure shown? If not, suggest how the compound might exist in this solution.

\[
\begin{align*}
\delta_H (\text{ppm}) & \quad 4.43 (2\text{H}, d, J 47 \text{ Hz}); \\
\delta_C (\text{ppm}) & \quad 83.5 (d, J 22 \text{ Hz}), 86.1 (d, J 171 \text{ Hz}), \text{ and } 176.1 (d, J 2 \text{ Hz}).
\end{align*}
\]

**Purpose of the problem**
To show how NMR spectra can reveal more than just the identity of a compound.

**Suggested solution**
The proton NMR spectrum is all right as we expect a large shift: from the chart on p. 276 of the textbook, we can predict 1.3 + 1 (C=O) + 2 (F) = 4.3 ppm and the coupling to fluorine is fine. The carbon NMR shows the carboxylate carbon at 176 ppm with a small coupling to F as it is so far away. The \(CH_2\) carbon is at 86.1 ppm with a huge coupling as it is joined directly to F. So far, so good. But what about the C=O group itself? We should expect it at about 200 ppm but it is at 83.5 with the expected intermediate coupling. It cannot be a carbonyl group at all. So what could have happened in D\(_2\)O? The obvious answer is that a hydrate is formed from this very electrophilic carbonyl group.
PROBLEM 7

An antibiotic isolated from a microorganism was crystallized from water and formed different crystalline salts in either acid or base. The spectroscopic data were:

- Mass spectrum 182 (M+, 9%), 109 (100%), and 74 (15%).
- \( \delta^H \) (ppm in D\(_2\)O at pH<1) 3.67 (2H, d, \( J7 \)), 4.57 (1H, t, \( J7 \)), 8.02 (2H, m), and 8.37 (1H, m).
- \( \delta^C \) (ppm in D\(_2\)O at pH<1) 33.5, 52.8, 130.1, 130.6, 130.9, 141.3, 155.9, and 170.2.

Suggest a structure for the antibiotic.

Purpose of the problem

Structure determination of a compound with biological activity from a natural source.

Suggested solution

The solubility and salt formation suggest the presence of both acidic and basic groups, perhaps CO\(_2\)H and NH\(_2\) as this is a natural compound. If so, the \( ^{13}C \) peak at 170.2 ppm is the CO\(_2\)H group. The five carbons in the sp\(^2\) region and protons at 8.0 and 8.4 suggest an aromatic ring, probably a pyridine. The mass spectrum gives an even molecular ion (182) so there must be another nitrogen atom beyond the one in the pyridine. The two sets of aliphatic protons are coupled and the large shift of the \( ^1H \) signal at 4.57 ppm suggests a proton between CO\(_2\)H and NH\(_3^+\) (pH <1). We have these fragments:

Presumably the aliphatic part must be X or Y, and that leaves just one oxygen atom for a formula of C\(_8\)H\(_{10}\)N\(_2\)O\(_3\) = 182. Only six of the ten H atoms show up in the NMR because the OH, NH\(_3^+\), and CO\(_2\)H protons all exchange rapidly at pH <1.

**PROBLEM 8**
Suggest structures for the products of these two reactions.

![Reaction diagram]

**Compound A:**
- m/z 170 (M+, 1%), 84 (77%), and 66 (100%);
- IR 1773, 1754 cm⁻¹;
- δ₂ (ppm, CDCl₃) 1.82 (6H, s) and 1.97 (4H, s);
- δ₁ (ppm, CDCl₃) 22, 23, 28, 105, and 169.

**Compound B:**
- m/z 205 (M+, 40%), 161 (50%), 160 (35%), 105 (100%), and 77 (42%);
- IR 1670, 1720 cm⁻¹;
- δ₂ (ppm, CDCl₃) 2.55 (2H, m), 3.71 (1H, t, J 6 Hz), 3.92 (2H, m), 7.21 (2H, d, J 8 Hz), 7.35 (1H, t, J 8 Hz), and 7.62 (2H, d, J 8 Hz);
- δ₁ (ppm, CDCl₃) 21, 47, 48, 121, 127, 130, 138, 170, and 172.

**Purpose of the problem**
The other important kind of structure determination: compounds isolated from a chemical reaction.

**Suggested solution**
Compound A is much simpler so we start with that. The two reagents are C₅H₆O₄ and C₅H₈O₂; these add up to C₁₀H₁₄O₆ (230) so 60 has been lost. This looks like C₅H₄O₂ or, less likely (because it must be saturated—it has no double bond equivalents), C₅H₈O. If the first is right, A is C₈H₁₀O₄ which at least fits the proton NMR. The IR suggests two carbonyl groups. The ¹³C NMR shows only one, but there must be some symmetry as there are only five signals for eight carbon atoms. The only unsaturation we have identified is the two carbonyl groups so the signal at 105 ppm is very strange. It must be next to two oxygen atoms to have such a large shift. Either 22 or 105 must...
be the C of CMe₂. C₈H₁₀O₄ would have four double bond equivalents, so the last two degrees of unsaturation must be rings. The cyclopropane provides one and the other must link the two oxygen atoms in the second part-structure. So we have:

```
O
|  |
|---|---|
| O | O |
```

This accounts for all the atoms in A so all we need to do is join these two fragments together! The carbonyls are arranged rather like those in cyclic anhydrides and the two carbonyl peaks must be the symmetric and antisymmetric stretches.

```
O
|  |
|---|---|
| O | O |
```

Compound B has nitrogen in it (it has an odd molecular weight) and clearly has a benzene ring from the NMR spectra, so we can put down PhN (= 91) as part of the structure. It also has two carbonyl groups (in the IR the one at 1670 cm⁻¹ looks like an amide) and they are both acid derivatives (you can see that in the ¹³C NMR). There are three aliphatic carbons, two CH₂s and one CH. Adding that together gives C₁₁H₁₀NO₃ = 188 so there is 17 missing that looks like OH. Since we need a second acid derivative and the OH is the only remaining heteroatom, it must be a carboxylic acid. Given that the CH is a triplet, it must be joined to one of the CH₂ groups and, as they are both multiplets, they must be joined to each other. There is one double bond equivalent to account for and that must be a ring. So we have:

```
O
|  |
|---|---|
| O | O |
```

To assemble these three fragments into a molecule we must plug the amide into the C₃ fragment and put the CO₂H group in the last free position. We can do this in two ways. Proton NMR distinguishes them. The end CH₃ is attached either to the nitrogen atom (which would give an estimated shift
of 3.2 ppm) or to the carbonyl group (estimated shift 2.2 ppm) of the amide. The observed value (3.92) fits the first better. A similar estimate for the CH gives the same answer and the first structure is indeed correct.

PROBLEM 9
Treatment of this epoxy-ketone with tosyl hydrazine gives a compound with the spectra shown below. What is its structure?

![Diagram](image)

**Purpose of the problem**
Further practice at structure determination, adding a curious chemical shift.

**Suggested solution**
The compound is an alkyne formed by a reaction known as the Eschenmoser fragmentation. It is not possible to assign all the $^{13}$C NMR signals but you can spot the alkyne carbons in the region 70–85 ppm and the alkyne CH at about 2 in the proton NMR. The triple bond signals in the IR at about 2150 cm$^{-1}$ is a give-away too. Alkyne C–H bonds are strong and come well above 3000 in the IR. The lack of vicinal coupling in the $^1$H NMR helps identify the rest of the skeleton of the molecule.

---

**PROBLEM 10**

Reaction of the epoxy-alcohol below with LiBr in toluene gave a 92% yield of compound A. Suggest a structure for this compound from the data:

- **mass spectrum** gives C₈H₁₂O;
- **ν** max (cm⁻¹) 1685, 1618;
- **δ**H (ppm) 1.26 (6H, s), 1.83, 2H, t, J 7 Hz), 2.50 (2H, dt, J 2.6, 7 Hz), 6.78 (1H, t (J 2.6 Hz), and 9.82 (1H, s);
- **δ**C (ppm) 189.2, 153.4, 152.7, 43.6, 40.8, 30.3, and 25.9.

**Purpose of the problem**

Further practice at structure determination including a change in the carbon skeleton—a ring contraction.

**Suggested solution**

The compound A is a simple cyclopentenal. The ¹³C NMR assignment is not at all certain.

---

PROBLEM 11
Female boll weevils (a cotton pest) produce two isomeric compounds that aggregate the males for food and sex. A few mg of two isomeric active compounds, grandisol and Z-ochtodenol, were isolated from 4.5 million insects. Suggest structures for these compounds from the data below. Signals marked * exchange with D₂O.

Z-ochtodenol:
m/z 154 (C₁₀H₁₈O), 139, 136, 121, 107, 69 (100%);
ν_max (cm⁻¹) 3350, and 1660;
δ_H (ppm) 0.89 (6H, s), 1.35-1.70 (1H, broad m), 1.41* (1H, s), 1.96 (2H, s), 2.06 (2H, t, J 6 Hz), 4.11 (2H, d, J 7 Hz), and 5.48 (1H, t, J 7 Hz).

Grandisol:
m/z 154 (C₁₀H₁₈O), 139, 136, 121, 109, 68 (100%);
ν_max (cm⁻¹) 3630, 3520, 3550, and 1642;
δ_H (ppm) 1.15 (3H, s), 1.42 (1H, dddd, J 1.2, 6.2, 9.4, 13.4 Hz), 1.35-1.45 (1H, m), 1.55-1.67 (2H, m), 1.65 (3H, s), 1.70-1.81 (2H, m), 1.91-1.99 (1H, m), 2.52* (1H, broad t, J 9.0 Hz), 3.63 (1H, dddd, J 5.6, 9.4, 10.2 Hz), 3.66 (1H, dddd, J 6.2, 9.4, 10.2 Hz), 4.62 (1H, broad s), and 4.81 (1H, broad s);
δ_C (ppm) 19.1, 23.1, 28.3, 29.2, 38.8, 41.2, 52.4, 59.8, 109.6, and 145.1.

Purpose of the problem
Further practice at structure determination of natural products.

Suggested solution
These are the structures. If you have other answers, check that these structures fit the data better.

---

PROBLEM 12
Suggest structures for the products of these reactions.

\[ \text{Compound A:} \]
\[ \text{C}_{10}\text{H}_{13}\text{OP, IR (cm}^{-1}\text{)} 1610, 1235; \]
\[ \delta (\text{ppm}) 6.5-7.5 (5\text{H, m}), 6.42 (1\text{H, t, } J 17 \text{ Hz}), 7.47 (1\text{H, dd, } J 17, 23 \text{ Hz}), \text{ and } 2.43 \]
\[ (6\text{H, d, } J 25 \text{ Hz}). \]

\[ \text{Compound B:} \]
\[ \text{C}_{12}\text{H}_{17}\text{O}_{2}, \text{ IR (cm}^{-1}\text{)} \text{ C-H and fingerprint only;} \]
\[ \delta (\text{ppm}) 7.25 (5\text{H, s}), 4.28 (1\text{H, d, } J 4.8 \text{ Hz}), 3.91 (1\text{H, d, } J 4.8 \text{ Hz}), 2.96 (3\text{H, s}), 1.26 \]
\[ (3\text{H, s}) \text{ and } 0.76 (3\text{H, s}). \]

Purpose of the problem
Structure determination of reaction products with extra twists: a nucleus with spin (P) and protons on the same carbon atom that are different in the NMR.

Suggested solution
The coupling constants $^3J_{PH}$ across the alkene are very large. Typically cis $^3J_{PH}$ is about 20 and trans $^3J_{PH}$ about 40. Geminal ($^2J_{PH}$) are also large but more variable. In B there is a stereogenic centre, meaning that the hydrogen atoms and methyl groups in the ring are different: they are either on the same side as MeO or the same side as Ph. (The term we will introduce in chapter 31 to describe such groups is 'diastereotopic'). We cannot say which H gives which signal.

**Problem 13**

Identify the compounds produced in these reactions. Warning! Do not attempt to deduce the structures from the starting materials, but use the data. These molecules are so small that you can identify them from $^1$H NMR alone.

Data for **A**: $C_4H_8; \delta_H (ppm)$ 5.35 (2H, s) and 1.00 (4H, s)

Data for **B**: $C_6H_10O; \delta_H (ppm)$ 3.00 (2H, s), 0.90 (2H, d, $J$ 3 Hz) and 0.80 (2H, d, $J$ 3 Hz)

Data for **C**: $C_4H_8O; \delta_H (ppm)$ 3.02 (4H, d, $J$ 5 Hz) and 1.00 (2H, quintet, $J$ 5 Hz).

**Purpose of the problem**

Structure determination of reaction products by $^1$H NMR alone.

**Suggested solution**

The very small shifts of cyclopropane protons may have worried you but they often have shifts of less than 1 ppm. Compounds **A** and **C** are simple enough but **B** may have amazed you. It is unstable but can be isolated and the two three-membered rings sit at right angles to each other, so as in problem 12 the protons on each side of the cyclopropane ring are different.
PROBLEM 14

The yellow crystalline antibiotic frustulosin was isolated from a fungus in 1978 and it was suggested the structure was an equilibrium mixture of A and B. Apart from the difficulty that the NMR spectrum clearly shows one compound and not an equilibrium mixture of two compounds, what else makes you unsure of this assignment? Suggest a better structure. Signals marked * exchange with D$_2$O.

Frustulosin:
m/z 202 (100%), 174 (20%);

\[ \nu_{\text{max}} \text{ (cm}^{-1}) \] 3279, 1645, 1613, and 1522;

\[ \delta_{\text{H}} \text{ (ppm)} \] 2.06 (3H, dd, J 1.0, 1.6 Hz), 5.44 (1H, dq, J 2.0, 1.6 Hz), 5.52 (1H, dq, J 2.0, 1.0 Hz), 4.5* (1H, broad s), 7.16 (1H, d, J 9.0 Hz), 6.88 (1H, dd, J 9.0, 0.4 Hz), 10.31 (1H, d, J 0.4 Hz), and 11.22* (1H, broad s);

\[ \delta_{\text{C}} \text{ (ppm)} \] 22.8, 80.8, 100.6, 110.6, 118.4, 118.7, 112.6, 125.2, 129.1, 151.8, 154.5, and 196.6.

**Warning!** This is difficult—after all, the original authors got it wrong initially.

**Hint:** How might the DBEs be achieved without a second ring?

**Purpose of the problem**

A serious and difficult determination of a natural product as a final challenge.

**Suggested solution**

Structure B is definitely wrong because the NMR shows only one methyl group, not two, and only one carbonyl group, not two. Structure A looks unlikely because it appears to be unstable, but that is not evidence. The NMR shows two protons on the same end of a double bond (at 5.44 and 5.52 ppm) with the characteristic small coupling, but they are coupled to a methyl group, presumably by allylic coupling, and the methyl group is too far away in B. But what is the signal at 80.8 in the $^{13}$C NMR? The ‘hint’ was meant to guide you towards suggesting an alkyne. That solves many of the problems even though the carbons of the alkene and the aromatic ring
cannot be assigned with confidence. At least the revised structure is one compound and not two.

**Suggested solutions for Chapter 19**

**PROBLEM 1**
Predict the orientation of HCl addition to these alkenes.

**Purpose of the problem**
Simple examples of addition with regioselectivity.

**Suggested solution**
The first and last alkenes have different numbers of substituents at each end of the alkene and will give the more stable, more highly substituted cation on protonation. The middle one has the same number of substituents (one) at each end but they are very different in kind. The secondary benzylic cation is preferred to the non-conjugated alternative.
PROBLEM 2
Suggest mechanism and products for these reactions.

Purpose of the problem
Checking that you understand the bromination mechanism.

Suggested solution
The question of what product is formed is easily answered as we know bromine adds trans to alkenes. The products are both racemic, of course, as all reagents are achiral and only the relative stereochemistry is shown.

The mechanism is bromonium ion formation by electrophilic attack of bromine on the alkene and trans opening of the bromonium ion by bromide ion.
PROBLEM 3
What will be the products of the addition of bromine water to these alkenes?

Purpose of the problem
Checking that you understand the bromonium ion mechanism with an external nucleophile.

Suggested solution
The bromonium ion is formed again but now water attacks as the nucleophile as it is in large excess as the solvent. If the alkene is unsymmetrical, water attacks the more substituted end of the bromonium ion (p. 441 of the textbook). In any case, it does so with inversion.
PROBLEM 4
By working at low temperature with one equivalent of buffered solution of a peroxo-acid, it is possible to prepare the monoepoxide of cyclopentadiene. Why are these precautions necessary and why does a second epoxidation not occur under these conditions?

Purpose of the problem
A more complicated electrophilic addition with questions of stability and selectivity to consider.

Suggested solution
One of the alkenes in the diene reacts in the usual way to give, first of all, the monoepoxide. The reaction can be stopped there only if the remaining alkene is less nucleophilic than the alkenes in cyclopentadiene. This is indeed the case because the HOMO of a diene is higher in energy than the HOMO of a simple alkene. The HOMO of the diene ($\Psi_2$) results from antibonding addition of the two separate $\pi$-orbitals, making the diene more reactive than an isolated alkene.

The other questions concern the low temperature, which favours the kinetic product and encourages epoxide formation on the remaining alkene. A by-product from the reaction is RCO$_2$H which could catalyse the opening of the epoxide to give a stable allyl cation (p. 336 in the textbook). The buffer prevents the mixture becoming too acidic.
PROBLEM 5
The synthesis of a tranquilizer uses this step. Give mechanisms for the reactions.

Purpose of the problem
An electrophilic addition followed by a substitution: revision of chapter 17.

Suggested solution
HBr adds to the alkene to form the tertiary cation that captures bromide ion.

The bromide is hydrolysed by water. This must be an $S_N1$ reaction as the bromide is tertiary and the nucleophile is water. The same cation is an intermediate in both reactions.
**PROBLEM 6**
Explain this result:

![Chemical structure diagram](image)

**Purpose of the problem**
An electrophilic addition followed by an elimination (revision of chapter 17) and a substitution (revision of chapter 15).

**Suggested solution**
Addition of bromine occurs first to give the trans dibromide in the usual way. Base then eliminates one of the bromides in an E2 reaction using the only available trans hydrogen atom. This gives a reactive allylic bromide (p. 336 in the textbook) that reacts with cyanide ion by a favourable S_N2 reaction to give the product.

![Mechanism diagram](image)

**PROBLEM 7**
Suggest a mechanism for the following reaction. What is the stereochemistry and conformation of the product? The product has these signals in its ^1^H NMR spectrum: δ_H 3.9 (1H, ddq, J 12, 4, 7) and δ_H 4.3 (1H, dd, J 11, 3).

![Chemical structure diagram](image)

**Purpose of the problem**
Drawing a mechanism for bromination of an alkene with an internal nucleophile, and revision of NMR.
Suggested solution

The mechanism is formation of the bromonium ion and nucleophilic attack by the OH group at the more substituted carbon. The product has one carbon with two methyl groups, of which one must be axial and one equatorial. The remaining substituted carbons, with a Br and a Me substituent, could be axial or equatorial: you might expect them to prefer to be equatorial but is there any evidence? The NMR spectrum shows that the two protons listed, whose large shift indicates that they are next to Br and O, both have large coupling constants. You will see details of the values of coupling constants in six-membered rings in chapter 31, but you already know that large $J$ values indicate parallel bonds (see pp. 293–4 of the textbook). This suggests that these C–H bonds are parallel (antiperiplanar) to their neighbours, something that is possible only if the C–H bonds are axial. The Br and the methyl group must therefore be equatorial.

PROBLEM 8

The two alkenes below can be converted into two regioisomers or two diastereoisomers as shown. Suggest reagents to achieve these transformations. What alternative starting material could you use to make the trans diol (bottom right)?

Purpose of the problem

Overview of methods for controlling selectivity in the reactions of alkenes.
Suggested solution

Hydration of the top alkene with aqueous acid goes via a carbocation intermediate, and would therefore give the product on the left. To get the product on the right we need a more roundabout method, involving hydroboration to place boron on the less hindered carbon and then oxidation to the alcohol (p. 446 of the textbook).

\[
\text{OH} \quad \text{H}_2\text{O}, \text{H}^+ \quad 1. \text{HBR}_2 \quad 2. \text{H}_2\text{O}_2, \text{NaOH}
\]

Using osmium tetroxide to add two hydroxyl groups to the second alkene will give the diastereoisomer on the left, because the mechanism ensures both O atoms add to the same side of the alkene (p. 442 of the textbook). To get the *trans* diol, we can make an epoxide with *m*-CPBA and then open it with water, an $S_{N}2$ reaction that proceeds with inversion of configuration.

\[
\text{OH} \quad \text{OH} \quad \text{OsO}_4 \quad \text{H}_2\text{O}, \text{H}^+ \quad \text{OH} \quad \text{OH}
\]

A possible alternative would be to start with the *cis* alkene: the product will be the diol shown, which, if we redraw it in an open chain conformation, is the same diol as the one that comes from the *trans* alkene via the epoxide.

\[
\text{OH} \quad \text{OH} \quad \text{OsO}_4 \quad \text{rotate about this bond} \quad \text{OH} \quad \text{OH}
\]
PROBLEM 1
Draw all possible enol forms of these carbonyl compounds and comment on their stability.

Purpose of the problem
Simple exercise in drawing enols with an extra twist.

Suggested solution
There is only one enol for the first compound and it might be stable because it is aromatic (two alkenes and one oxygen giving two electrons each, making six in all).

The second compound has more possibilities, one of which is very stable indeed as it has two benzene rings. We haven’t drawn the mechanism for each enolization this time but note the different reaction arrows for tautomerism (equilibrium) and delocalization (two ways of drawing the same compound).

Aromaticity is discussed in chapter 7 of the textbook, pages 157–162. Compounds in which lone pairs contribute to the aromatic sextet are introduced on page 162, but also have two whole chapters devoted to them (chapters 29 and 30). These chapters are more advanced than you need at this stage.
**PROBLEM 2**

The proportions of enol in a neat sample of the two ketones below are rather different. Why is this?

![Chemical structures](image)

**Purpose of the problem**

Thinking about the stability of enols bearing stabilizing substituents.

**Suggested solution**

The first compound is an ordinary ketone with its strong C=O bond and so the less stable enol with its weaker C=C bond is present in only tiny amounts. The second compound has the special 1,3-relationship between two carbonyl groups that means a very stable enol. The stability comes from a major reason—conjugation of C=C and C=O—and a minor reason—intramolecular hydrogen bonding.
**PROBLEM 3**
The NMR spectrum of this dimethyl ether is complicated: the two MeO groups are different as are all the hydrogen atoms on the rings. However the diphenol has a very simple NMR spectrum—there are only two types of proton on the rings marked 'a' and 'b' on the diagram. Explain.

---

**Purpose of the problem**
Exploring the way that tautomerism leads to equivalence.

**Suggested solution**
The protons in the ether are obviously all different as it has no symmetry. Tautomerization interconverts carbonyl groups and enols, and can make either of the enols in the diphenol into a carbonyl group and can make the carbonyl group into an enol, so all structures are equivalent. If this proton transfer (note that it is not a delocalization) is fast on the NMR timescale, all the H's will appear in one signal and all the H's will appear in another signal.

---

The idea that some interconversions take place too fast to be detected by NMR (they are fast on the NMR timescale) is covered in the blue boxes on p. 363 and p. 374 of the textbook.
PROBLEM 4

Suggest mechanisms for these reactions:

1. Mg
2. PhCN
3. H⁺, H₂O

Purpose of the problem

Revision of mechanisms plus exploration of reactions involving enols.

Suggested solution

The first reaction starts with acetal hydrolysis and the product is an enone that is not conjugated. It can become conjugated in acid solution via the enol.

The second sequence starts with the reaction of a nitrile with a Grignard reagent and the hydrolysis of the product to a ketone; this is mentioned on pp. 220 and 231 of the textbook. The bromination in acid solution makes use of the only enol possible.
**Problem 5**

Suggest mechanisms for these reactions and explain why these products are formed.

![Chemical structures](image)

**Purpose of the problem**

Making sure that you understand why enols usually react through carbon but sometimes react through oxygen.

**Suggested solution**

The same ketone reacts in similar acidic conditions with different selectivity according to the electrophile. The bromination occurs at carbon as we should expect but the anhydride reacts at oxygen. So we can draw mechanisms to suit the product.

![Mechanisms](image)

Acid anhydrides, being carbonyl electrophiles, respond to charge density (they are ‘hard’ electrophiles) and react well with oxygen nucleophiles. Bromine, by contrast, is uncharged and unpolarized (it is a ‘soft’ electrophile) and reacts well with neutral nucleophiles such as alkenes.
PROBLEM 6
1,3-Dicarbonyl compounds such as A are usually mostly enolized. Why is this? Draw the enols available to compounds B-E and explain why B is 100% enol but C, D, and E are 100% ketone.

Purpose of the problem
Exploring enols of different kinds of 1,3-dicarbonyl compounds—an important class of enolizable compounds.

Suggested solution
Compound A is mostly enol because only the enol is delocalized over five atoms. A minor reason for this particular compound is the intramolecular hydrogen bond in the enol.

You might also have pointed out that there is another equally good enol that has the other carbonyl group enolized. The two enols are tautomers of each other and of the keto-ester.

That compound B is completely enolized shows that conjugation is much more important than hydrogen bonding, which is impossible with B. However, B has extra conjugation from the lone pairs on the extra oxygen atoms.
The remaining compounds have problems with enolization. Compound C can form an enol on the side away from the other carbonyl group, but cannot form an enol between the two ketones as it would be a 'bridgehead alkene'. These do not generally exist as the four substituents around the alkene cannot become planar.

Compound D seems to have a perfectly reasonable enol. But the very large tert-butyl group, which would be out of the plane in the diketone, would have to lie in the plane if the enol were formed. The four-membered ring in E is already strained enough with two sp² atoms having 90° bond angles. The enol would have three such atoms and this is too much strain.

**PROBLEM 7**

Attempted nitrosation of this carboxylic acid leads to formation of an oxime with loss of CO₂. Why?

**Purpose of the problem**

Nitrosation of an enol, followed by an unusual step.

**Suggested solution**

Sodium nitrite in acid generates NO⁺, which usually reacts with enols to form nitroso compounds and then oximes (p. 464 of the textbook). Let's
follow the mechanism through with this acid. Enolization gives the nucleophile, which picks up NO⁺.

This nitroso compound can’t tautomerize because there are no adjacent protons, so instead the compound forms an oxime by losing CO₂. We can draw a cyclic mechanism for this:

PROBLEM 8
This molecule is a perfumery compound with an intense flowery odour, but it isomerizes rapidly in base to its odourless diastereoisomer. Why?

Purpose of the problem
The stereochemical consequences of enolization in a cyclohexane.

Suggested solution
Base will catalyse the enolization of our aldehyde, and when the carbonyl compound reforms, the proton could return to either the face it left from or the other side, allowing the compound to intercovert with its diastereoisomer. If we draw the compounds in their chair conformation, you can see that while the starting aldehyde has an axial substituent (which must be the less bulky CHO group), the diastereoisomer formed through enolization has two equatorial substituents and is more stable. In fact, the equilibrated mixture contains 92% of the equatorial product.
Solutions for Chapter 20 – Formation and reactions of enols and enolates

\[
\begin{align*}
\text{CHO group axial} & \quad \text{both equatorial: more stable}
\end{align*}
\]
This page intentionally left blank
Suggested solutions for Chapter 21

PROBLEM 1
All you have to do is to spot the aromatic rings in these compounds. It may not be as easy as you think and you should give some reasons for questionable decisions.

Thyroxine: human hormone regulating metabolic rate
Aklavinone: tetracycline antibiotic
Colchicine: anti-cancer agent from the autumn crocus
Calistephin: natural red flower pigment
Methoxatin: coenzyme from bacteria living on methane

Purpose of the problem
Simple exercise in counting electrons with a few hidden tricks.

Suggested solution
Truly aromatic rings are marked with bold lines. Thyroxine has two benzene rings—obviously aromatic—and that’s that. Aklavinone also has two aromatic benzene rings and we might argue about ring 2. It has four electrons as drawn, and you might think that you could push electrons round from the OH groups to give ring 2 six electrons as well. But if you try it, you’ll find you can’t.
Colchicine has one benzene ring and a seven-membered conjugated ring with six electrons in double bonds (don’t count the carbonyl electrons as they are out of the ring). It perhaps looks more aromatic if you delocalize the electrons and represent it as a zwitterion. Either representation is fine.

Methoxatin has one benzene ring and one pyrrole ring—an example of an aromatic compound with a five-membered ring. The six electrons come from two double bonds and the lone pair on the nitrogen atom. The middle ring is not aromatic—even if you try drawing other delocalized structures, you can never get six electrons into this ring.
PROBLEM 2
First, as some revision, write out the detailed mechanism for these steps.

\[
\text{HNO}_3 + \text{H}_2\text{SO}_4 \rightarrow \text{NO}_2 \\
\text{NO}_2 \rightarrow \text{NO}_2
\]

In a standard nitration reaction with, say, \( \text{HNO}_3 \) and \( \text{H}_2\text{SO}_4 \), each of these compounds forms a single nitration product. What is its structure? Explain your answer with at least a partial mechanism.

**Purpose of the problem**

Revision of the basic nitration mechanism and extension to compounds where selectivity is an issue.

**Suggested solution**

The basic mechanisms for the formation of \( \text{NO}_2^+ \) and its reaction with benzene appear on p. 476 of the textbook. Benzoic acid has an electron-withdrawing substituent so it reacts in the meta position. The second compound is activated in all positions by the weakly electron-donating alkyl groups (all positions are either ortho or para to one of these groups) but will react at one of the positions more remote from the alkyl groups because of steric hindrance.

\[
\text{CO}_2\text{H} \rightarrow \text{CO}_2\text{H} \\
\text{Me} \rightarrow \text{Me} \rightarrow \text{O}_2\text{N}
\]

The remaining two compounds have competing ortho,para-directing substituents but in each case the one with the lone pair of electrons (N or O) is a more powerful director than the simple alkyl group. In the first case nitrogen directs ortho but in the second oxygen activates both ortho and para and steric hindrance makes the para position marginally more reactive.
PROBLEM 3

How reactive are the different sites in toluene? Nitration of toluene produces the three possible products in the ratios shown. What would be the ratios if all the sites were equally reactive? What is the actual relative reactivity of the three sites? You could express this as \(xy:1\) or as \(a:b:c\) where \(a+b+c = 100\). Comment on the ratio you deduce.

Purpose of the problem

A more quantitative assessment of relative reactivities.

Suggested solution

As there are two ortho and two meta sites, the ratio if all were equally reactive would be 2:2:1 \(o:m:p\). The observed reactivity is 30:2:37 or 15:1:18 or 43:3:54 depending on how you expressed it. The ortho and para positions are roughly equally reactive because the methyl group is electron-donating. The para is slightly more reactive than the ortho because of steric hindrance. The meta position is an order of magnitude less reactive because the intermediate is not stabilized by electron-donation (\(\sigma\)-conjugation) from the methyl group.
PROBLEM 4

Draw mechanisms for these reactions and explain the positions of substitution.

**Purpose of the problem**

More advanced questions of orientation with more powerful electron-donating groups.

**Suggested solution**

The OH group has a lone pair of electrons and dominates reactivity and selectivity. Steric hindrance favours the para product in the first reaction. The bromination has to occur ortho to the phenol as the para position is blocked.
The second example has two Friedel-Crafts alkylations with tertiary alkyl halides. The first occurs para to bromine, a deactivating but ortho,para-directing group (see p. 489 in the textbook), preferring para because of steric hindrance. The second is a cyclization—the new ring cannot stretch any further than the next atom.

PROBLEM 5
Nitration of these compounds gives products with the ¹H NMR spectra shown. Deduce the structures of the products and explain the position of substitution. WARNING: do not decide the structure by saying where the nitro group 'ought to go'! Chemistry has many surprises and it is the evidence that counts.

Purpose of the problem
Revision of the relationship between NMR and substitution pattern.
Suggested solution

The first product has only eight hydrogens so two nitro groups must have been added. The molecule is clearly symmetrical and the coupling constant is right for neighbouring hydrogens so a substitution on each ring must have occurred in the para position. Note that the hydrogen next to the nitro group has the larger shift. We can deduce that each benzene ring is an ortho,para-directing group on the other because the intermediate cation is stabilized by conjugation.

The hydrogen count reveals that the next two products are mono-nitro compounds. There are two hydrogens ortho to nitro in the second compound and one of them also has a typical ortho coupling to a neighbouring hydrogen while the other has only a small coupling (2 Hz) which must be a meta coupling. Substitution has occurred para to one of the chlorines and ortho to the other. The chlorines are ortho,para-directing thus activating all remaining positions so steric hindrance must explain the site of nitration.

The third compound has the extra complication of couplings to fluorine. The coupling of 7 Hz shown by one hydrogen and 6 Hz shown by the other must be to fluorine as they occur once only. The symmetry of the compound and the typical ortho coupling between the hydrogens (8 Hz) shows that para substitution must have occurred.
PROBLEM 6
Attempted Friedel-Crafts acylation of benzene with t-BuCOCl gives some of the expected ketone A as a minor product, as well as some t-butylbenzene B, but the major product is the substituted ketone C. Explain how these compounds are formed and suggest the order in which the two substituents are added to form compound C.

Purpose of the problem
Detailed analysis of a revealing example of the Friedel-Crafts reaction.

Suggested solution
The expected reaction to give A is a simple Friedel-Crafts acylation with the usual acylium ion intermediate.

Product B must arise from a t-butyl cation and the only way that might be formed is by loss of carbon monoxide from the original acylium ion. Such a reaction happens only when the resulting carbocation is reasonably stable.
The main product C comes from the addition of both these electrophiles, but which adds first? The ketone in A is deactivating and *meta* directing but the *t*-butyl group in B is activating and *para*-directing so it must be added first.

That answers the question but you might like to go further. Both A and C are formed by the alkylation of benzene as the first step. The decomposition of the acylium ion is evidently *faster* than the acylation of benzene. However, when B reacts further, it is mainly by acylation as only a small amount of di-*t*-butyl benzene is formed. Evidently the decomposition of the acylium ion is *slower* than the acylation of B! This is not unreasonable as the *t*-butyl group accelerates electrophilic attack—but it is a dramatic demonstration of that acceleration.

**PROBLEM 7**

Nitration of this heterocyclic compound with the usual HNO₃/H₂SO₄ mixture gives a single nitration product with the "H NMR spectrum shown below. Suggest which product is formed and why.

- δ₃4 (2H, t, J 7 Hz)
- 3.68 (2H, t, J 7 Hz)
- 6.45 (1H, d, J 8 Hz)
- 7.28 (1H, broad s)
- 7.81 (1H, d, J 1 Hz)
- 7.90 (1H, dd, J 8, 1 Hz)

**Purpose of the problem**

Revision of NMR and an attempt to convince you that the methods of chapter 21 can be applied to molecules you’ve not met before.

**Suggested solution**

The two 2H triplets and the broad NH signal show that the heterocyclic ring is intact. One nitro group has been added to the benzene ring. The proton at 7.81 with only one small (*meta*) coupling must be between the nitro group and the other ring and is marked on the two possible structures.
You could argue that NH is ortho, para-directing and so the second structure is more likely. But this is a risky argument as the reaction is carried out in strong acid solution where the nitrogen will mostly be protonated. It is safer to use the predicted $\delta_H$ from tables. Here we get:

<table>
<thead>
<tr>
<th>Proton</th>
<th>ortho</th>
<th>meta</th>
<th>para</th>
<th>predicted $\delta_H$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$H^+$</td>
<td>NO₂ = +0.95</td>
<td>CH₂ = –0.14</td>
<td>NH = –0.25</td>
<td>7.73</td>
</tr>
<tr>
<td>$H^+$</td>
<td>NO₂ = +0.95</td>
<td>NH = –0.75</td>
<td>CH₂ = –0.06</td>
<td>7.31</td>
</tr>
</tbody>
</table>

There’s not much difference but $H^+$ at 7.73 is closer to the observed 7.81, so it looks as though the small amount of unprotonated amine directs the reaction.

PROBLEM 8
What are the two possible isomeric products of this reaction? Which structure do you expect to predominate? What would be the bromination product from each?

Purpose of the problem
Getting you to think about alternative products and possible reactions on compounds that haven’t been made (yet).

Suggested solution
The reaction is a Friedel-Crafts cyclization, as you could have deduced by the simple loss of water. The resulting cation could cyclize in two ways, arbitrarily called A and B. Steric hindrance suggests that A would be the more likely product.
Bromination will go either ortho or para to the methoxy group: A has two different positions ortho to the OMe, but the para position is blocked. The least sterically hindered position gives a 1,2,4,5-tetrasubstituted ring. B might give a mixture of ortho and para substitution.
PROBLEM 9
On p. 479 of the textbook we explain the formation of 2,4,6-tribromophenol by bromination of phenol in water. It looks as though we can go no further as all the ortho and para positions are brominated. But we can if we treat the tribromo-compound with bromine in an organic solvent. Account for the formation of the tetrabromo-compound.

![Reaction Diagram]

The product is useful in brominations as it avoids using unpleasant Br₂. Suggest a mechanism for the following bromination and account for the selectivity.

![Reaction Diagram]

Purpose of the problem
Exploration of interesting chemistry associated with electrophilic substitution on benzene rings.

Suggested solution
Phenol is so reactive that the fourth bromine adds in the para position. Now the molecule has a problem as there is no hydrogen on that carbon to be lost. So the phenolic hydrogen is lost instead. It is surprising but revealing that this loss of aromaticity is preferred to the alternative bromination at the meta position.
In the second reaction, one of the reactive bromines in the \textit{para} position is transferred to the amine. It could have added \textit{ortho} or \textit{para} to the NMe\textsubscript{2} group but CF\textsubscript{3} is small and NMe\textsubscript{2} is large, because the two methyl groups lie in the plane of the ring, so steric hindrance rules. The other product is recovered tribromophenol.

\begin{itemize}
  \item Note that the meta directing effect of the deactivating CF\textsubscript{3} group is irrelevant (see p. 491 of the textbook).
\end{itemize}

\textbf{PROBLEM 10}

How would you make each of the following compounds from benzene?

\begin{itemize}
  \item \begin{tikzpicture}
    \node (A) at (0,0) {\text{O}};
    \node (B) at (1,0) {\text{NH}_2};
    \draw[->] (A) -- (B);
  \end{tikzpicture}
  \item \begin{tikzpicture}
    \node (A) at (0,0) {\text{Br}};
    \node (B) at (1,0) {\text{NO}_2};
    \draw[->] (A) -- (B);
  \end{tikzpicture}
  \item \begin{tikzpicture}
    \node (A) at (0,0) {\text{Br}};
    \node (B) at (1,0) {\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_3};
    \draw[->] (A) -- (B);
  \end{tikzpicture}
\end{itemize}

\textbf{Purpose of the problem}

Choosing a synthetic route, taking into account the directing effects of the substituents involved.

\textbf{Suggested solution}

The first compound has a ketone substituent, which is electron-withdrawing and therefore \textit{meta}-directing, and an amino group, which is electron-donating and therefore \textit{ortho,para}-directing. Aromatic amino groups are best made by reduction of nitro groups, which are also meta directing, so there are two possibilities. We can either start with a Friedel-Crafts acylation of benzene to give the ketone, which we can nitrate in the \textit{meta} position and then reduce, or we can start by nitrating benzene, then do the acylation and then reduce. Either is a reasonable solution.
The second compound has a bromo substituent, which is ortho,para-directing, and a meta-directing nitro group. We need the para relationship, so we must put the bromine in first, then nitate.

Finally, a compound with two para-directors arranged meta to one another. This may seem a problem, but we must introduce the alkyl group by Friedel-Crafts acylation and reduction, since primary alkyl groups cannot be introduced by Friedel-Crafts alkylation. The acyl group will be meta directing, so that solves both problems. First acylate, then brominate, then reduce.
Suggested solutions for Chapter 22

PROBLEM 1
Draw a mechanism for this reaction. Why is base unnecessary?

\[
\text{PhPH}_2 + \overset{\text{excess}}{\overset{\text{CN}}{\text{CN}}} \rightarrow \text{Ph} \overset{\text{P}}{\text{P}} \overset{\text{CN}}{\text{CN}}
\]

Purpose of the problem
Simple example of conjugate addition with a nucleophile from the second row of the periodic table.

Suggested solution
The phosphine is a good soft nucleophile with a high energy lone pair, well able to add in a conjugate fashion without help. In particular, the neutral phosphine does not need to be converted into its anion. The intermediate is a good base and removes a proton from itself, not necessarily intramolecularly.

\[
\text{PhPH}_2 \rightarrow \text{PhP} \overset{\text{CN}}{\text{CN}} \text{and repeat}
\]
PROBLEM 2
Which of the two routes suggested here would actually lead to the product?

Purpose of the problem
Do you understand the essentials of conjugate addition? Can you say when it won’t happen?

Suggested solution
To get the product, the chloride must add in a conjugate fashion and ethyl Grignard in a direct fashion that removes the carbonyl group. Conjugate addition can happen only if the carbonyl group is intact so HCl must be added first.

In the other sequence, EtMgBr is likely to add to the carbonyl group direct and further addition of HCl may either substitute on the allylic alcohol or add the ‘wrong way round’ to the alkene.
**PROBLEM 3**

Suggest reasons for the different outcome of each of these reactions. Your answer must of course be mechanistically based.

![Chemical Structures]

**Purpose of the problem**

A reminder of the reactions possible with enones.

**Suggested solution**

The three reactions are: enolization and trapping with silicon, direct addition with a hard irreversible nucleophile, and conjugate addition with a softer reversible nucleophile.
PROBLEM 4
Suggest a mechanism for this reaction.

**Purpose of the problem**
Combination of conjugate addition and electrophilic aromatic substitution.

**Suggested solution**
The weakly nucleophilic benzene has evidently added in conjugate fashion to the enone in a kind of Friedel-Crafts reaction and we can use the Lewis acid to make the enone into the necessary cation.

PROBLEM 5
What is the structure of the product of this reaction and how is it formed? It has δC 191, 164, 132, 130, 115, 64, 41, 29 and δH 2.32 (6H, s), 3.05 (2H, t, J 6 Hz), 4.20 (2H, t, J 6 Hz), 6.97 (2H, d, J 7 Hz), 7.82 (2H, d, J 7 Hz), 9.97 (1H, s). You should obviously interpret the spectra to get the structure.

**Purpose of the problem**
Revision of NMR with an exercise in nucleophilic aromatic substitution.

**Suggested solution**
Summing the formulae of the two starting materials shows that this is a substitution of fluoride (the product is the sum of the starting materials less...
HF). The aldehyde is still there (from the IR and the proton at 10 ppm) so the spectra are best interpreted by this structure:

That suggests a simple nucleophilic aromatic substitution by the addition-elimination mechanism with both F and CHO assisting the first step.

PROBLEM 6
Suggest a mechanism for this reaction, explaining the selectivity.

Purpose of the problem
Introduction to the mechanism and selectivity of nucleophilic aromatic substitution.

Suggested solution
Both ortho and para positions are activated by the ketone towards nucleophilic attack by the amine, but the para position is preferred because of steric hindrance between the large heterocyclic ring and the ketone. The
substitution works because those five fluorine atoms make the ring very electron-deficient.

PROBLEM 7

Pyridine is a six-electron aromatic system like benzene. You have not yet been taught anything systematic about pyridine (that will come in chapter 29) but see if you can work out why 2- and 4-chloropyridines react with nucleophiles but 3-chloropyridine does not.

Purpose of the problem

Extension of the ideas on nucleophilic aromatic substitution into new compounds.

Suggested solution

The problem is to find somewhere to park the negative charge in the intermediate and the only possible place is on the pyridine nitrogen atom. This is easy with 2- and 4-chloropyridine but impossible with 3-chloropyridine. Using a general nucleophile:
Amine formation by this reaction is particularly important as you will see in chapters 29 and 30. The mechanism is the same with a few proton transfers.

**PROBLEM 8**

How would you carry out these two conversions?

**Purpose of the problem**

Application of nucleophilic aromatic substitution in synthesis.

**Suggested solution**

Usually you would think of introducing NH$_2$ by nitration and reduction (chapter 21), but the regioselectivity is wrong for the first reaction: the methoxy group will direct nitration ortho to itself. An alternative is to introduce both NH$_2$ and CN as nucleophiles, but the ring is unactivated so we can’t use the addition-elimination mechanism (there is nowhere for the negative charge to go). The successful alternatives are electrophilic aromatic substitution followed by diazonium salt formation and the benzyne method. Here are two possible routes. Nitration will insert the nitro group ortho to
the more strongly electron-donating MeO group. Reduction, diazotization and substitution with copper cyanide by the $S_{N1}$ mechanism gives one product.

![Chemical structure]

The other product could come from chlorination, elimination to give a benzyne, addition of amide anion to put the anion ortho to MeO (p. 524 in the textbook) and protonation.

![Chemical structure]

**PROBLEM 9**

Suggest mechanisms for these reactions, pointing out why you chose the pathways.

![Chemical structures]

**Purpose of the problem**

Studies in selectivity and choosing the right mechanism.

**Suggested solution**

In the first reaction, the nucleophile adds in the ‘wrong’ position (i.e. where the leaving group isn’t) so a benzyne mechanism is likely. Notice that the
nucleophile and the benzyne are formed with the same strong base, that the anion is recycled and that the nucleophile adds to the benzyne to put the negative charge next to OMe (p. 524 in the textbook).

The second reaction is a straightforward substitution by the addition-elimination mechanism activated by the nitro group. The amino group is a spectator.

**PROBLEM 10**

When we discussed reduction of cyclopentenone to cyclopentanol, we suggested that conjugate addition of borohydride must occur before direct addition of borohydride: in other words, the scheme below must be followed. What is the alternative scheme? Why is the scheme shown definitely correct?

**Purpose of the problem**

Serious thinking about mechanisms is an advantage when reactions get more complex.

**Suggested solution**

The alternative scheme would be to reduce the ketone first and the alkene second. This order must be wrong though, because simple alkenes are nucleophilic and are not reduced by NaBH₄. NaBH₄ is a nucleophilic reducing agent and attacks alkenes only if they are conjugated with an
electron-withdrawing group. The conjugate addition must always occur first so as to keep the carbonyl group intact for the second step.

PROBLEM 11
Stirring thioacetic acid with acrolein (propanaldehyde) in acetone gives a compound with the NMR data shown below. What is the compound?

δ\textsubscript{H}: 2.28 (3H, s), 3.58 (2H, d, J 8), 4.35 (1H, td, J 8, 6), 6.44 (1H, t, J 6), 7.67 (1H, d, J 6).
δ\textsubscript{C}: 23.5, 31.0, 99.3, 144.2, 196.5.

Purpose of the problem
Using NMR to gain insight into a conjugate addition.

Suggested solution
The product formula is the sum of the reaction partners, and all 5 C and 8 H atoms are visible in the NMR spectra, so this looks like an addition reaction. The \textsuperscript{13}C NMR tells us that there are two alkene carbons and one carbonyl, and the proton NMR clearly shows the aldehyde has gone. But it can’t be direct addition to the C=O group, because the coupling pattern isn’t right for a terminal alkene. The product is in fact the enol formed from conjugate addition of the sulfur, which is stable under these conditions. The low coupling constant across the alkene tells us it’s formed unusually as the Z-isomer, probably because of an intramolecular proton transfer from the thioacid to the new OH group. The anhydrous conditions in dry acetone prevent the enol from tautomerizing back to the aldehyde.

This work is described by Lukas Hintermann in *J. Org. Chem.*, 2012, 77, 11345.
Suggested solutions for Chapter 23

Several problems in this chapter ask you to suggest ways to carry out conversions of one molecule into another. We always give one possible answer and sometimes comment on alternatives but you should realize that there are usually many possible ‘right’ answers to questions of this sort. Make sure you understand the principle behind the question and, if your answer is very different from ours, check with someone with experience of synthesis.

PROBLEM 1
How would you convert this bromo-aldehyde chemoselectively into the two products shown?

Purpose of the problem
A simple exercise in chemoselectivity and protection.

Suggested solution
You would like to add an organometallic reagent to go to the right and that’s very simple as no protection is needed. A Grignard reagent will do the job.

The other product demands more care to avoid the reactions we have just done. The aldehyde needs to be protected, as an acetal, say, before we make
the Grignard reagent from the aryl bromide. Then we can add to RCHO, and deprotect with acid, and we have our product.

PROBLEM 2
How would you convert this lactone selectively into either the hydroxyacid or the unfunctionalized acid?

Purpose of the problem
Exploration of chemoselectivity.

Suggested solution
The conversion into the hydroxy-acid is just hydrolysis and can be carried out in aqueous base. Conversion into the unfunctionalized acid demands selective reduction of the C–O at the secondary benzylic centre. Possibilities include catalytic hydrogenolysis (p. 539 in the textbook) or HBr followed by C–Br reduction.

**PROBLEM 3**
Predict the products of Birch reduction of these aromatic compounds.

![Chemical structures](image)

**Purpose of the problem**
Exploring the principles of Birch reduction.

**Suggested solution**
In each case a unique product results if you draw a dianion intermediate placing the electron-withdrawing groups where they can stabilize the negative charges, and put the electron-donating groups on the alkenes, where they don’t destabilize the negative charges.

![Chemical reactions](image)

**PROBLEM 4**
How would you carry out these reactions? In some cases more than one step may be required.

![Chemical reactions](image)

**Purpose of the problem**
Reduction, selectivity, and protection in the same sequence.
The final product was used to make an analogue of thromboxane, a human blood clotting agent, by M. Hayashi and group, *Tetrahedron Lett.*, 1979, 3661.

**Suggested solution**

Every step is straightforward except the final reduction where a less reactive ester must be reduced in the presence of a more reactive ketone. Protection is the answer and an acetal is suitable.

PROBLEM 5

How would you convert this nitro compound into the two products shown? Explain the order of events with special regard for reduction steps.

Purpose of the problem

Reduction, selectivity, and protection in two related sequences.

**Suggested solution**

The nitro group must be reduced to an amino group and cyclized onto the ketone or the carboxylic acid. Reductive amination (pp. 234–7 in the textbook) allows the amine to cyclize onto the more electrophilic ketone.

Forming the six-membered ring requires more control. Protection of the ketone (say as the acetal) before reduction will give the six-membered cyclic amide. Now the amide carbonyl must be reduced with LiAlH₄ (p. 236 in the textbook) and the ketone deprotected. There are many good alternative answers to this problem.
PROBLEM 6
Why is this particular amine formed by reductive amination here?

Purpose of the problem
Extending the concept of reductive amination by combining it with deprotection and cyclization.

Suggested solution
The two acetals will be hydrolysed at pH 5.5 to give the amine a choice between cyclization to one or other of the two aldehydes.

Cyclization to a five-membered ring is preferred to cyclization to a (strained) four-membered ring so reductive amination occurs to the right and not to the left (as drawn). Cyanoborohydride is stable under the weakly acidic conditions and does not reduce the remaining aldehyde.
PROBLEM 7

Account for the chemoselectivity of the first reaction and the stereoselectivity of the second. A conformational drawing of the intermediate is essential.

\[
\begin{align*}
\text{O} & \quad \text{HO} & \quad \text{OH} & \quad \text{H}_2, \text{Pd/C} \\
\text{O} & \quad \text{H} & \quad \text{O} & \quad \text{O} & \quad \text{O} & \quad \text{H}_2, \text{Pd/C} \\
\text{Me} & \quad \text{O} & \quad \text{Me} & \quad \text{O} & \quad \text{H}
\end{align*}
\]

Purpose of the problem

Extending chemoselectivity into more subtle distinctions and conformational analysis.

Suggested solution

The two ketones are different only because one is conjugated. Since acetal formation is a thermodynamically controlled reversible reaction, the one that is formed retains the enone as the stabilizing effect of conjugation can be retained. A conformational diagram of the intermediate shows that there is inevitably one axial oxygen atom belonging to the acetal preventing the bottom face of the alkene from getting close to the catalyst. The axial methyl group is further away and more in the plane of the alkene. Hydrogen is delivered from the top face and the observed product results.

The conformation of decalin is discussed on pp. 378–9 of chapter 16 of the textbook. The ‘flattening’ effect of the alkene is dealt with in chapter 32.
**PROBLEM 8**

How would you convert this diamine to either of these two protected derivatives?

\[
\begin{align*}
\text{H}_2\text{N} & \text{NH}_2 \\
\rightarrow & \\
\text{H}_2\text{N} & \text{NH} \text{Boc} \quad \text{or} \quad \text{BocHN} \text{NH}_2
\end{align*}
\]

**Purpose of the problem**

Using protecting groups to reveal reactive groups selectively.

**Suggested solution**

The Boc group is a common acid-sensitive protecting group for amines, and making the first derivative is easy because the amine attached to the primary carbon is less hindered and more reactive. Treating the diamine with one equivalent of ‘Boc anhydride’ (Boc\(_2\)O) gives the correctly protected product.

\[
\begin{align*}
\text{H}_2\text{N} & \text{NH}_2 \\
\rightarrow & \\
\text{H}_2\text{N} & \text{NH} \text{Boc}
\end{align*}
\]

The second is more of a challenge, because we have to protect the less reactive amino group. The solution is first to protect with a different protecting group: Cbz will do, using CbzCl (benzyl chloroformate) and base. Now the other amino group can be protected with Boc, and finally the Cbz protecting group removed by hydrogenation. Other protecting groups might be all right too, but they have to be removable without using acid, which would remove the Boc group.

\[
\begin{align*}
\text{H}_2\text{N} & \text{NH}_2 \\
\rightarrow & \\
\text{H}_2\text{N} & \text{NH} \text{Cbz} \\
\rightarrow & \\
\text{BocHN} & \text{NH} \text{Cbz} \\
\rightarrow & \\
\text{BocHN} & \text{NH}_2
\end{align*}
\]

This chemistry was used by chemists in Bordeaux and Manchester to build some new polymeric structures out of the two different amine products.
Suggested solutions for Chapter 24

PROBLEM 1
Two routes are proposed for the preparation of this amino-alcohol. Which do you think is more likely to succeed and why?

![Chemical structures]

**Purpose of the problem**
Practical application of the choice of reagent to ensure the correct regioselectivity in a conjugate addition.

**Suggested solution**
Either route might give the product but enals are more likely to undergo direct addition to the carbonyl group rather than conjugate addition while conjugated esters are better at conjugate addition. So the ester is probably better.

![Chemical structures]

PROBLEM 2
Predict the products of these reactions.

![Chemical structures]

**Purpose of the problem**
Practice at predicting the regioselectivity of a direct or conjugate addition.
Suggested solution

Both reactions involve addition of organometallic compounds to unsaturated carbonyl compounds. The key difference is the metal. With Cu(I) as catalyst, the Grignard reagent will give conjugate addition in the first case. MeLi will give direct addition in the second.

PROBLEM 3

Explain the different regioselectivity in these two brominations of 1,2-dimethylbenzene.

Purpose of the problem

Regioselectivity in electrophilic aromatic substitution and in radical substitution.

Suggested solution

AlCl₃ is a commonly used Lewis acid in electrophilic aromatic substitution reactions. Here it activates the bromine to form the electrophile ‘Br⁺’, which attacks the aromatic ring. Methyl groups are ortho,para directors, so any of the four unsubstituted positions could be attacked, but steric hindrance directs the first bromine to go to one of the positions that does not lead to a 1,2,3-trisubstituted ring.

Now we have three ortho,para directors, and bromine (with its lone pairs) is the strongest, so the next bromine will go ortho to the bromine in the less sterically hindered of the two possibilities.
In the presence of light, bromine's weak Br–Br bond undergoes homolysis, and Br' radicals are formed. One of these can abstract a hydrogen atom, breaking the weakest C–H bond. The methyl groups' C–H bonds are weaker than those of the phenyl ring because the benzyl radical that forms is delocalized into the aromatic ring. The benzyl radical attacks another molecule of bromine, and the cycle continues.

The mechanism is shown here for the first bromination; the same thing can happen on the other methyl group.

**PROBLEM 4**

The nitro compound below was needed for the synthesis of an anti-emetic drug. It was proposed to make it by nitration of the hydrocarbon shown. How successful do you think this would be?

![Diagram of nitration reaction]

**Purpose of the problem**

Predicting regioselectivity in electrophilic aromatic substitution where directing effects are more subtle.

**Suggested solution**

The standard conditions for nitration generate the electrophile NO$_2^+$, and to get the product shown here, this species has to attack the ring as shown below. The intermediate cation looks quite all right, since the positive charge can be delocalized even into the other ring.
What about the alternatives? A similar cation is formed if the electrophile attacks the position labelled ‘1’, but the nitro group is in a more hindered position here, so we don’t expect this to contribute much to the product mixture. Position ‘2’ gives the cation shown below, which although perfectly feasible as an intermediate, does not benefit from the same degree of stabilization as the one in the reaction we want (it can’t be delocalized into the other ring). Position 4 is similar but more hindered. Overall we can reasonably expect the reaction to give the product we want.

**PROBLEM 5**  
Comment on the regioselectivity and chemoselectivity of the reactions shown below.

**Purpose of the problem**  
Regioselectivity in electrophilic aromatic substitution with an intramolecular electrophile: an important reaction for making heterocycles.

**Suggested solution**  
The reaction of an aldehyde with an amine gives an imine, and in acid (HCl), protonation gives an iminium ion, the electrophile that attacks the aromatic ring. The iminium ion is tethered to the ring, so it has only two choices of reaction site, since it can’t reach any further than the positions
ortho to the tether. The one it chooses is the less hindered. It is also para to an electron-donating methoxy group, so the reaction works well.

In the second case, there is only one methoxy group, and both the positions ortho to the tether are meta to it, where it can't activate substitution. The positions ortho to itself, where it can activate, are too far away for the iminium to reach, so no substitution takes place. Presumably the iminium ion forms, but it is just hydrolysed back to the aldehyde.

PROBLEM 6
Identify A and B and account for the selectivity displayed in this sequence of reactions.

Purpose of the problem
Analysing selectivity in a useful ring-forming sequence.

Suggested solution
The Friedel-Crafts acylation in the first step is controlled by the bromo substituent, which is an ortho,para director: here we get para selectivity as usual for steric reasons. Work through the mechanism and you find a ketoacid as the product A.
The next step is the reduction we introduced on p. 540 of the textbook, the ‘Wolff-Kishner’ reduction. The mechanism is there so we need not repeat it here; the product is the acid B (or, rather, its potassium salt). Now adding acid forms a ring in another Friedel-Crafts acylation. The electrophile must be the acylium ion: usually Friedel-Crafts acylations need more than just strong acid, but this one is fast because it is intramolecular. What about regioselectivity? Well, the only positions the electrophile can reach are ortho to the carbon chain, so it must react there (they are both the same) even though that means it has to attack meta to the Br group. It’s still ortho to the alkyl chain though, which is ortho,para directing.

**PROBLEM 7**

The sequence of reactions below shows the preparation of a compound needed for the synthesis of a powerful anti-cancer compound. Explain the regioselectivity of the reactions. Why do you think two equivalents of BuLi are needed in the second step?

**Purpose of the problem**

Explaining regioselectivity in ortholithiation reactions.
Suggested solution

Both reactions involve ortholithiation—deprotonation of the aromatic ring to form an intermediate aryllithium. As we explain on pp. 563–4 of the textbook, the deprotonation occurs where the BuLi can be ‘guided in’ by coordinating oxygen atoms. The methoxymethyl acetal, with its two oxygen atoms, is very good at doing this, so we expect deprotonation at one of the two positions ortho to this group. The other acetal is also a complexing group, so the deprotonation happens in between the two oxygen atoms.

In the second step, deprotonation can again take place next to the methoxymethyl group. Two equivalents of BuLi are needed because the most acidic proton is in fact one of the protons of the methyl group: a benzyllithium forms first, and then a more reactive aryllithium. When the electrophile (DMF) is added, it reacts only with the last formed, more basic anion.

Phenyllithiums are more basic than benzyllithiums, because in benzyllithiums the ‘anion’ is conjugated with the ring; in phenyllithiums the ‘anion’ is perpendicular to the \( \pi \) system (like the lone pair in pyridine).

Selectivity in the reactions of dianions is described on p. 547 of the textbook.
PROBLEM 8
Comment on the regioselectivity and chemoselectivity of the reactions in the sequence below.

\[
\begin{align*}
\text{N} & \quad \text{OH} \\
\text{N} & \quad \text{OH} \\
\text{O} & \quad \text{MeO} \\
\text{BnBr} & \quad \text{N} \quad \text{OH} \\
\text{Ph} & \quad \text{Br} \\
\text{NaBH}_4, \text{EtOH} & \quad \text{N} \quad \text{OH} \quad \text{Ph} \\
\text{Cl} & \quad \text{MeO} \quad \text{CO} \\
\text{NaHCO}_3 & \quad \text{MeO} \quad \text{CO} \\
\end{align*}
\]

Purpose of the problem
Practice using simple principles of reactivity to explain why nucleophiles and electrophiles choose to react at particular sites, and using your knowledge of reactivity to deduce mechanisms for some unfamiliar reactions.

Suggested solution
Benzyl bromide is a good electrophile and it reacts well with alkoxides to make ethers. With neutral alcohols however the substitution is very slow, so only the more nucleophilic (and more basic) pyridine nitrogen is attacked, to make a pyridinium salt.

The pyridinium salt is a bit like an iminium ion, so sodium borohydride attacks it at the C=N+ bond to make a neutral enamine. Looking at the product, you can see that another reduction must take place as well, but enamines are nucleophilic, so the borohydride can’t attack directly. What must happen instead is that the enamine is protonated to make another iminium, which can then be reduced. The final double bond is safe from attack, since it is an isolated, electron-rich alkene.
In the final step, another electrophile is added: it’s an acid chloride, though a slightly unusual one, usually called ‘methyl chloroformate’. As in the first step, the most nucleophilic atom is the pyridine N, so we use its lone pair to attack the carbonyl group and displace chloride. Now we have to lose the benzyl group, but the only reagent we have to help us is the chloride we just lost. Chloride is a nucleophile—a weak one, but powerful enough to attack the cationic species we have just generated. Which is the site most susceptible to nucleophilic substitution? The benzylic carbon, quite reasonably, because of the accelerating effect of the adjacent π system. Nucleophilic substitution here gives the final product.

**PROBLEM 9**

Explain the regioselectivity displayed in this synthesis of the drug tanomastat.

**Purpose of the problem**

Explaining why moderately complex molecules choose to react selectively.
Suggested solution

The first reaction is a Friedel-Crafts acylation. There are two rings and two carbonyl groups, so we must explain first of all the choice between each of these pairs. One ring is chlorinated: chlorine has a deactivating effect on electrophilic aromatic substitution, so the non-chlorinated ring reacts. The two carbonyls differ in that the top one is (a) less hindered and (b) not conjugated, both of which contribute to its greater reactivity. There is also the question of regioselectivity in the way that the acylation occurs at the \( \text{para} \) position of the non-chlorinated ring. Aryl substituents are ortho,para directing, because they can delocalize the positive charge formed from attack in this way; steric factors favour the \( \text{para} \) over the \( \text{ortho} \) positions.

In the second step, thiophenol gives the conjugate addition, rather than the direct addition product to either carbonyl group. Sulfur nucleophiles are soft, and this is typical behaviour for thiols.

PROBLEM 10

This compound is needed as a synthetic precursor to the drug etalocib. Suggest a synthesis. \textit{Hint}: consider using nucleophilic aromatic substitution.

Purpose of the problem

Thinking about regioselectivity and reactivity in the synthesis of a moderately complex aromatic compound.
Suggested solution

There are lots of ortho relationships in this compound! And somehow we have to join the two aromatic rings together to make an ether. This can only really be done by nucleophilic aromatic substitution, so we need to look for an electron-withdrawing group to help us. The nitrile is in the right place, provided we have a leaving group (such as fluoride) ortho to it. So our last step can be as shown here:

![Chemical structure](image1)

To make the left hand ring we have to consider what methods are available to introduce the three substituents we have. It’s always easier to add C-substituents than O-substituents, so we might consider how to alkylate the phenol below. Both the OH and OMe groups are ortho,para directing, so we could consider a Friedel-Crafts reaction, but there are problems with this approach. One is the usual problem with primary alkyl groups—we would have to do an acylation and then reduce. Another is more serious: the less hindered positions the other side of the OMe or OH groups are also activated, so we will have a regioselectivity problem. The solution used by the chemists making this compound for the first time was to use ortholithiation, making the dianion with two equivalents of BuLi and making use of the fact that two O substituents guide the BuLi in to deprotonate the position between them.

![Chemical structure](image2)

See pp. 514–520 of the textbook for a reminder of nucleophilic aromatic substitution.

The work is described by Sawyer et al., J. Med. Chem. 1993, 38, 4411.
This page intentionally left blank
**Suggested solutions for Chapter 25**

**PROBLEM 1**
Suggest how these compounds might be made by alkylation of an enol or enolate.

![Chemical structures](image)

**Purpose of the problem**
An exercise in choosing good routes to simple compounds.

**Suggested solution**
As you can see from the carbonyl groups in these compounds, it is pretty obvious which is the new bond to be made. In both cases, the electrophile will need to be an allylic halide. These are good electrophiles for S_N2 reactions so they will work well here. We need to use the electrophile twice in the first case and the enolate is that of diethyl malonate. The second case will require an enol or enolate equivalent to prevent self-condensation: a silyl enol ether (p. 595 in the textbook) or an enamine (p. 591 in the textbook) is ideal. If you use a silyl enol ether, don’t forget the Lewis acid!

![Reaction scheme](image)

- The reason why allylic halides make good electrophiles is discussed in the textbook on p. 341.
PROBLEM 2
How might these compounds be made using alkylation of an enol or enolate as one step in the synthesis?

Purpose of the problem
An exercise in using enolate chemistry to make carbonyl compounds disguised as acetals.

Suggested solution
The only functional group in either compound is an acetal. Cyclic acetals are made from diols and carbonyl compounds so we need to have a look at the deprotected molecules before taking any further decisions.

If we are going to use enolate chemistry, we have to make the diols by reduction of carbonyl compounds. As both diols have a 1,3-relationship between the OH groups, the carbonyl precursors will be the very enolizable 1,3-dicarbonyl compounds, which can be alkylated and reduced. We have chosen arbitrarily to use ethyl esters here, so we should use ethoxide as the base in the alkylation step.
PROBLEM 3
How might these amines be prepared using enolate-style alkylation as part of the synthesis?

Purpose of the problem
An exercise in using enolates and related compounds in the synthesis of amines.

Suggested solution
The first amine could be made by reduction of a nitrile, and that could be made by alkylation of the ‘enolate’ from PhCH₂CN.

The second amine could be made by reductive amination of a ketone so we need to make the ketone by alkylation of an enolate. You could have chosen various specific enol equivalents for this job—we have chosen an enamine.
PROBLEM 4
This attempted enolate alkylation does not give the required product. What has gone wrong? What products would actually be formed? How would you make the required product?

Purpose of the problem
An exercise in trouble-shooting—it is important for you to recognize what might go wrong and how to get round the problem.

Suggested solution
The intention was obviously to make the lithium enolate of the aldehyde and to alkylate it with i-PrCl, but BuLi will attack the aldehyde carbonyl group rather than remove a proton. Even if it did make some of the enolate, the enolate would react with the aldehyde and self-condense (p. 590 in the textbook).

There is also a problem with i-PrCl: it is a secondary halide and chloride is the worst leaving group among the halogens Cl, Br, I—it is prone to elimination rather than substitution reactions. To make the required product, an aza-enolate (p. 593 in the textbook) or a silyl enol ether (p. 595 in the textbook) would be a better bet.
PROBLEM 5

Draw mechanisms for the formation of this enamine, its reaction with the alkyl halide, and the hydrolysis of the product.

Purpose of the problem

Exploration of the details of enamine formation and reaction. These are often misunderstood.

Suggested solution

The first step of the mechanism for enamine formation is not acid-catalysed—amines need no help in attacking carbonyl compounds. But the dehydration step is acid-catalysed as HO⁻ is not a good leaving group. The selectivity for elimination into the unbranched chain is because the enamine is planar and there would be a bad steric clash between the methyl group and the nitrogen substituents (all of which are in the same plane) if elimination occurred the other way.

The mechanism of enamine formation is given on p. 233 of the textbook.
The reaction of the enamine with the alkyl halide goes as expected—these very good S_{N}2 electrophiles work particularly well with enamines and the first product under the reaction conditions is another enamine.

Finally the enamine is hydrolysed by reprotonation to the same iminium salt and addition of water. These steps are the exact reverse of what happens in enamine formation.

**PROBLEM 6**

How would you produce specific enols or enolates at the points marked with the arrows (not necessarily starting with the ketones themselves)?

**Purpose of the problem**

First steps in making enol(ate)s with regiochemical control.
Suggested solution

The last two ketones have two different $\alpha$-positions so there is a good chance of controlling enol formation from the parent ketone. But the first ketone has two primary $\alpha$-positions and the difference appears only in the two $\beta$-positions. The obvious solution is conjugate addition and trapping (described in the textbook on p. 603). The thermodynamic enol is needed from the second ketone and direct silylation is a good bet. The third requires kinetic enolate formation and LDA is a good way to do that.

![Chemical structures showing the formation of enolates through conjugate addition and trapping, followed by silylation and LDA activation.]

PROBLEM 7

How would the enol(ate) equivalents we have just made react with (a) bromine and (b) a primary alkyl halide $RCH_2Br$?

Purpose of the problem

Moving on from the formation of enol(ate)s to their reactions.

Suggested solution

The two silyl enol ethers will react well with bromine and won’t need Lewis acid catalysis as bromine is such a powerful electrophile—so powerful that it might be dangerous to react the lithium enolate directly with bromine and making the silyl enol ether first might be advisable.

![Chemical structures showing the reaction of the silyl enol ethers with bromine and alkyl halides.]
In the reaction with the primary alkyl halide, the boot is on the other foot as there will be a good reaction with the lithium enolate but no reaction with the more stable silyl enol ethers. Lewis acid won't help here either as primary cations are unstable. Preliminary conversion into a lithium enolate or a 'naked' enolate (using fluoride ion) would be better.

PROBLEM 8
Draw a mechanism for the formation of this imine:

Purpose of the problem
Revision of the often forgotten mechanism for imine formation.

Suggested solution
The main points in the mechanism are addition of the amine to the carbonyl group without catalysis and dehydration of the intermediate with acid catalysis.

The mechanism of imine formation is given on p. 230 of the textbook.
PROBLEM 9
How would the imine from problem 8 react with the reagents below? Draw mechanisms for each step: the reaction with LDA, the addition of BuBr, and the work-up.

Purpose of the problem
Checking you know how to make and use an aza-enolate.

Suggested solution
LDA removes the most acidic proton of the imine so that the Li atom is transferred to the nitrogen atom to give the aza-enolate. Electrophiles, even alkyl halides, then add to the ‘enolate’ position and the work-up is hydrolysis of the imine with aqueous acid.

PROBLEM 10
What would happen if you tried this short cut for the reactions in problems 8 and 9?

Purpose of the problem
Reminder of the problems with lithium enolates of aldehydes.
Suggested solution

Some aldehydes can be converted directly into lithium enolates but this is not usually very successful because the rate of reaction of the lithium enolate with the very electrophilic aldehyde is too great and at least some aldol reaction will occur.

\[ \text{RCHO} \xrightarrow{\text{LDA}} \text{RCH}_2\text{OLi} \xrightarrow{\text{RCHO}} \text{RCH}_2\text{OH} \]

PROBLEM 11

Suggest mechanisms for these reactions.

1. \( \text{EtO}_2\text{C} \rightarrow \text{EtO}_2\text{C} \) (NaOEt, EtOH)
2. \( \text{NaOH, H}_2\text{O} \)
3. \( \text{H}^+, \text{heat} \) ester hydrolysis

Purpose of the problem

Learning to unravel complicated looking sequences that are quite easy when you get into them.

Suggested solution

Double alkylation of the malonate enolate gives the four-membered ring and hydrolysis and decarboxylation gives the carboxylic acid product.

\[ \text{EtO}_2\text{C} \xrightarrow{\text{Br}} \text{EtO}_2\text{C} \xrightarrow{\text{H}_2\text{O}} \text{EtO}_2\text{C} \xrightarrow{\text{H}^+, \text{heat}} \text{HO}_2\text{C} \]

The problem of aldol reactions competing with alkylations is mentioned in the green box on p. 584 and on p. 590 of the textbook. The aldol reaction itself is the subject of chapter 26.

The hydrolysis-decarboxylation sequence is explained on p. 597 of the textbook.
**PROBLEM 12**
How does this synthesis of a cyclopropyl ketone work?

Enols and enolates are involved in an unlikely looking sequence that you can work out if you persist.

**Suggested solution**
Alkylation of the enolate with the epoxide gives an alkoxide that cyclizes to give the lactone.

Now $S_{N2}$ opening of the protonated lactone with the soft nucleophile (bromide ion) gives the $\gamma$-bromoketone that cyclizes through its enolate. The formation of three-membered rings is favoured kinetically.
PROBLEM 13
Give the structures of the intermediates in the following reaction sequence and mechanisms for the reactions.

Purpose of the problem
A reminder that enolate-like intermediates can be formed at nitrogen as well as carbon providing that an oxygen atom can carry the negative charge.

Suggested solution
The first base removes the proton from nitrogen to make an enolate-like intermediate that reacts at nitrogen. Now that the NH is blocked, the second base makes the amide enolate that is alkylated on carbon.
Suggested solutions for Chapter 26

**PROBLEM 1**
The aldehyde and the ketone below are self-condensed with aqueous NaOH so that an unsaturated carbonyl compound is the product in both cases. Give a structure for each product and explain why you think this product is formed.

Purpose of the problem

Drawing mechanisms for the simplest of aldols: self-condensation of aldehydes and ketones.

Suggested solution

In both cases only one compound can form an enolate and only one compound—the same one—can be the electrophile. This is very obvious with the aldehyde.

With the ketone, there is a question of regioselectivity in enolate formation, but the aldol product can lose water only if the enolate from the methyl group is the nucleophile. If we draw both enolates and combine them with the ketone in an aldol reaction, it is clear that one can dehydrate as it has two enolizable H atoms but the other cannot dehydrate as it has no H atoms on the vital carbon atom (in grey). The mechanism is the same as the one with the aldehyde and the elimination in both cases is by the E1cB mechanism.

See p. 399 and p. 616 in the textbook for the E1cB mechanism.
PROBLEM 2
Propose mechanisms for the ‘aldol’ and dehydration steps in the termite defence compound presented on p. 623 in the textbook.

Purpose of the problem
Revision of elimination reactions and the mechanism for ‘an aldol that can’t go wrong.’

Suggested solution
The nitro group is twice as electron-withdrawing as a carbonyl group so it will readily form an ‘enolate.’ It cannot self-condense as nucleophilic attack rarely occurs on nitro groups so it attacks the aldehyde instead. Notice that the alkoxide product is basic enough to deprotonate another molecule of nitromethane so the reaction is catalytic in base.

The elimination step involves acylation of the hydroxyl group and an E1cB elimination again driven by the ‘enolate’ of the nitro group. Note that pyridine, a weak base, is strong enough.

See p. 587 in the textbook: a nitro group acidifies adjacent C–H bonds as much as two carbonyl groups.

E1cB elimination is on pp. 399 and 616 in the textbook.
PROBLEM 3
How would you synthesize the following compounds?

[Chemical structures are shown]

**Purpose of the problem**
Application of the aldol reaction to make unsaturated carbonyl compounds.

**Suggested solution**
Just find the conjugated alkene and so find the hidden carbonyl group. In the first case, cyclohexanone provides two enols to react with benzaldehyde. The phenyl rings in the product lie *trans* to the carbonyl group so that they can be planar.

In the second case, more options are available. Our solution suggests using a Wittig reaction for the first as we need the enolate of acetaldehyde (p. 628 in the textbook), and malonic acid for the second (p. 630 in the textbook). There are many alternatives such as using an aldol reaction for the first step, but with an excess of acetaldehyde, to compensate for self-condensation.
PROBLEM 4
How would you use a silyl enol ether to make this aldol product? Why is it necessary to use this particular intermediate? What would be the products be if the two carbonyl compounds were mixed and treated with base?

Purpose of the problem
Exploring control, and the lack of it, in different styles of aldol reaction.

Suggested solution
This is about the most difficult type of aldol reaction: two slightly different aldehydes, both enolizable, both capable of self-condensation. The only solution is to couple the silyl enol ether of one aldehyde with the other aldehyde using a Lewis acid as catalyst. This gives the aldol itself that can be dehydrated to the enal.

Without this control, each aldehyde would self-condense and would condense with the other aldehyde giving four products in unpredictable amounts. One of the cross-condensation products is, of course, the enal we are trying to make.
**PROBLEM 5**

In what way does this reaction resemble an aldol reaction? Comment on the choice of base. How can the same product be made without using phosphorus chemistry?

\[
\begin{align*}
\text{EtO} & \quad \text{O} \\
\text{(EtO)}_2P & \quad \text{O}
\end{align*}
\]

\[
\text{EtCHO} \quad \text{K}_2\text{CO}_3 \quad \text{water}
\]

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{(EtO)}_2P & \quad \text{O}
\end{align*}
\]

**Purpose of the problem**

Showing that there are reactions closely related to the aldol reaction that give similar products.

**Suggested solution**

The formation of an alkene and the loss of phosphorus are typical of a Wittig reaction but the formation of an unsaturated carbonyl compound using an enolate is very like an aldol reaction. The phosphonate ester reagent is also like a 1,3-dicarbonyl compound, with P replacing C. The very weak base used shows how stable the enolate must be. The enolate attacks the aldehyde, perhaps to form an intermediate oxyanion.

\[
\begin{align*}
\text{(EtO)}_2P & \quad \text{O} \\
\text{O} & \quad \text{O}
\end{align*}
\]

There is no doubt that the next intermediate is formed. It is a stable four-membered ring (phosphorus likes 90° bond angles). Finally phosphorus captures oxygen (the P–O bond is very strong) eliminating the alkene in its preferred trans stereochemistry.

\[
\begin{align*}
\text{(EtO)}_2P & \quad \text{O} \\
\text{O} & \quad \text{O}
\end{align*}
\]

The final product could also be made by the aldol condensation of a silyl enol ether and the same aldehyde. The silyl enol ether is the less substituted possibility so it will have to be made via the lithium enolate. The product will be the aldol itself and this can be dehydrated to the enone with TsOH.

This type of Wittig reaction was introduced on p. 628 of the textbook.
PROBLEM 6
Suggest a mechanism for this attempted aldol reaction. How could the aldol product be made?

Purpose of the problem
A demonstration of one way that aldol reactions with formaldehyde may fail.

Suggested solution
The aldol reaction appears to have taken place and then the ketone has been reduced. The only possible reducing agent is more formaldehyde and the reduction takes place by the Cannizarro reaction (p. 620 in the textbook). The aldol can be successful if a weaker base such as Na₂CO₃ is used as the Cannizarro requires a dianion intermediate.
PROBLEM 7
The synthesis of six-membered ketones by intramolecular Claisen condensation was described in the chapter where we pointed out that it doesn’t matter which way round the cyclization happens as the product is the same.

Strangely enough, five-membered heterocyclic ketones can be made by a similar sequence. The starting material is not symmetrical and two cyclized products are possible. Draw structures for these products and explain why it is unimportant which is formed.

Purpose of the problem
To make sure you understand how extra ester groups can solve apparently complex acylation problems.

Suggested solution
The cyclization can occur in two different ways to give two different products as either ester can form an enolate that attacks the other in an intramolecular acylation. We should draw the two products.
Though these compounds are different, each gives the same ketone after hydrolysis and decarboxylation as the ketone carbonyl group is on the same position in the ring in both compounds.

**PROBLEM 8**

Attempted acylation at carbon often fails. What would be the actual products of these attempted acylations and how would you successfully make the target molecules?

![Reaction schemes showing attempted acylations and products](image)

**Purpose of the problem**

Revision of simple enolate reactions (chapter 20) and encouragement to clear thinking about what happens when you put carbonyl compounds in basic solutions.

**Suggested solution**

In the first case we want the aldehyde to form an enolate and then attack the ester. The first part is all right: the aldehyde will form an enolate more readily than the ester. But under these equilibrating conditions, the small amount of enolate that is formed will react faster with the aldehyde than with the less electrophilic ester. The aldehyde will self-condense in an aldol reaction.

![Aldol reaction scheme](image)

To make the required compound we shall need to convert the aldehyde into a specific enol equivalent. There are various alternatives of which the best are an enamine or a silyl enol ether. Esters fail to acylate either and an acid chloride should be used instead. Don’t forget the Lewis acid if you use the silyl enol ether.
The enolate formation in the second example is a separate step and will work well because the two carbonyl groups cooperate in forming a stable enolate and NaOMe is quite strong enough to convert the diketone entirely into the enolate. The problem is the acylation step. With a sodium enolate and a reactive acylating agent such as PhCOCl, a charge-controlled (hard/hard) interaction will occur at the oxygen atom to give an enol ester.

The escape route from this problem suggested in the chapter (p. 648) was to use a lithium or magnesium enolate. Magnesium is chelated by the two oxygen atoms of the stable enolate and blocks attack there so that C-acylation occurs even with acid chlorides.
PROBLEM 9
Acylation of the phenolic ketone gives compound A, which is converted into an isomeric compound B in base. Cyclization of B gives the product shown. Suggest mechanisms for the reactions and structures for A and B.

Purpose of the problem
Predicting products of acylation reactions. This is always more difficult than just drawing mechanisms but here you might work backwards from the final product as well as forwards.

Suggested solution
The starting material is C_8H_8O_2 so A has an extra C_7H_4O. This looks like the addition of PhCOCl with the loss of HCl. The most obvious reaction is acylation of the phenolic oxygen rather than enolate formation as OH is much more acidic than CH and pyridine is a weak base. This phenol is unusually acidic as the carbonyl group helps to stabilize the anion. Compound A is simply the benzoate ester of the phenol. Treatment with KOH isomerizes A to B and this is the heart of the problem. An intramolecular acylation of the only possible enolate can be catalysed by KOH even though it produces only a little enol as cyclization to form a six-membered ring is so easy.

The final step is acid-catalysed and clearly involves the attack of the phenolic OH group on one of the ketones. This intramolecular reaction much prefers to form a six-membered ring rather than a strained four-membered ring, and dehydration gives an aromatic ring—two electrons each from the double bonds and two from a lone pair on oxygen making six in all. Drawing the delocalization may help you to see this.
PROBLEM 10

How could these compounds be made using the acylation of an enol or enolate as a key step?

Purpose of the problem

Practice in using acylation at carbon to make compounds.

Suggested solution

The first problem has two possible solutions by direct acylation, labelled A and B in the diagram. A would have to be controlled as the straight chain ester could self-condense. B needs no control as only the ketone can enolize. Diethyl carbonate (EtO)₂CO is more electrophilic than a ketone and only the wanted product can enolize again and form a stable enolate under the reaction conditions. However, route B adds only one carbon atom.

Route A can be realized with either a lithium enolate or a silyl enol ether, as explained on p. 649 of the textbook, using an acid chloride as the electrophile.
Route B requires the synthesis of the ketone starting material and this could be done by Grignard methods (chapter 9) or by acylation of an organo-copper compound with an acid chloride. Acylation with diethyl carbonate requires no special control.

**PROBLEM 11**

Suggest how the following reactions might be made to work. You will probably have to select a specific enol equivalent.

Purpose of the problem

Making reactions work is an important part of organic chemistry.

Suggested solution

The first reaction is a standard acylation of an aldehyde creating a quaternary centre. You might have used a silyl enol ether but an enamine, such as one made from a cyclic secondary amine, is probably better.
The second example might just go with simple base (MeO⁻) catalysis as the conjugated ketone enolate is much more stable than the enolate of the ester. However, it’s probably safer to use a lithium enolate (or a silyl enol ether—though you’d then have to use an acid chloride as the electrophile).

**PROBLEM 12**
Base-catalysed reaction between these two esters allows the isolation of a product A in 82% yield.

The NMR spectrum of this product shows that two species are present. Both show two 3H triplets at about $\delta_H = 1$ and two 2H quartets at about $\delta_H = 3$ ppm. One has a very low field proton and an ABX system at 2.1–2.9 with $J_{AB} 16$ Hz, $J_{AX} 8$ Hz, and $J_{BX} 4$ Hz. The other has a 2H singlet at 2.28 and two protons at 5.44 and 8.86 coupled with $J_{13} 13$ Hz. One of these protons exchanges with D₂O. Any attempt to separate the mixture (for example by distillation or chromatography) gives the same mixture. Both compounds, or the mixture, on treatment with ethanol in acid solution give the same product B.

Compound B has IR 1740 cm⁻¹, $\delta_H$ 1.15–1.25 (four t, each 3H), 2.52 (2H, ABX system $J_{AB} 16$ Hz), 3.04 (1H, X of ABX split into a further doublet by $J 5$ Hz), and 4.6 (1H, d, $J 5$ Hz). What are the structures of A and B?

**Purpose of the problem**
Revision of enol structure by NMR and a further exploration of what happens to acylation products.
**Suggested solution**

Only the diester can form an enolate and ethyl formate (HCO₂Et—it is half an ester and half an aldehyde) is much more electrophilic than the diester. We should expect the diester to be acylated by ethyl formate.

The compound A₁ fits the formula for A and the ¹H NMR spectrum of the compound with the low field signal (assigned to the CHO proton). This structure would also show an ABX system in its ¹H NMR spectrum. But what is the other compound (A₂)? It is obviously in equilibrium with A₁ and it lacks both the aldehyde proton and the ABX system and it sounds like an enol. Compound A₁ is chiral so the CH₂ group appears as an ABX system but A₂ is not chiral so the CH₂ group is a singlet. Here are the structures with their NMR assignments. In both cases the 3H triplets and 2H quartets are ethyl groups.

Treatment with acidic ethanol simply makes the acetal from the aldehyde group of A₁. Since A₁ and A₂ are in equilibrium, all A₂ is eventually converted into A₁ and then into B. Compound B is again chiral so the ABX system reappears with further coupling of X with the acetal proton. There are now four triplets and four quartets from the four ethyl groups.
PROBLEM 1
Suggest a mechanism for this reaction, commenting on the selectivity and the stereochemistry.

Purpose of the problem
The opportunity to explore the consequences of the intramolecular version of an important reaction.

Suggested solution
The ylid forms in the usual way but can’t reach across the ring to attack the carbonyl group directly so it has to do conjugate addition instead. It also has to attack from the top face as it is tethered there. Completion of the cyclopropane forming reaction leaves the sulfur still attached to the angular methyl group. Raney nickel reduces the C–S bond (this reagent is commonly used for this purpose). This reaction shows that simple sulfonium ylids can do conjugate addition—they just prefer to add to carbonyl groups if that possibility is available.

PROBLEM 2

Explain the regiochemistry and stereochemistry of this reaction.

\[
\begin{align*}
\text{Br} & \quad \text{O} \\
& \quad \text{Me}_2\text{S} \quad \text{CO}_2\text{Et} \quad \rightarrow \\
& \quad \text{EtO}_2\text{C} \\
\end{align*}
\]

Purpose of the problem

Exploration of sulfur ylid chemistry.

Suggested solution

The ylid is stabilized by conjugation with the ester group—you can think of it also as an enolate. We can expect reversible addition to the carbonyl group and hence conjugate addition under thermodynamic control. The stereochemistry of the ring junction is inevitable: only a \textit{cis} ring can be made (a \textit{trans}-fused ring would be too strained). The interesting centre is that of the ester on the three-membered ring. It too is in a more stable configuration: on the outside of a folded molecule. The intermediate is probably a mixture of diastereoisomers, but as the conjugate addition is reversible the cyclopropane may be formed by cyclization of only the diastereoisomer that can give the more stable product.
The first reaction is an acetal exchange controlled by entropy: three molecules go in and four come out (the product, two molecules of methanol and one of water). We show just part of the mechanism.
Now the sulfur atoms work to stabilize an anion (organolithium) formed by deprotonation. Alkylation and hydrolysis with a mercury catalyst gives the product.

PROBLEM 4
Suggest a mechanism by which this cyclopropane might be formed.

Attempts to repeat this synthesis on the related compound below led to a different type of product. What is different this time?

Purpose of the problem
Can you disentangle a curious variation on a simple mechanism?
**Suggested solution**

The first reaction is a straightforward cyclopropane formation with a sulfoxonium ylid and a conjugated ketone. The only unusual feature, the MeO group, makes no difference.

\[
\begin{align*}
\text{Ph} & \quad \text{Ph} \\
\text{O} & \quad \text{OMe} \\
\text{MeO} & \quad \text{SMe}_2\text{CH}_2\text{O} \\
\text{Ph} & \quad \text{Ph} \\
\text{O} & \quad \text{OMe} \\
\text{O} & \quad \text{Br}
\end{align*}
\]

In the second example, the bromine atom and the phenolic OH evidently do make a difference. No doubt the reaction starts in the same way and a cyclopropane is formed. Under the reaction conditions, the phenol will exist as an anion and this displaces the bromine. This unusual S_N2 reaction at a tertiary centre is possible because of activation by the carbonyl group.

\[
\begin{align*}
\text{Ph} & \quad \text{OH} \\
\text{Br} & \quad \text{Me}_2\text{SC}_2\text{H}_2\text{O} \\
\text{Ph} & \quad \text{Ph} \\
\text{O} & \quad \text{Br}
\end{align*}
\]

**PROBLEM 5**

Deduce the structure of the product of this reaction from the NMR spectra and explain the stereochemistry. Compound A has \(\delta_H 0.95 (6H, d, J 7 \text{ Hz}), 1.60 (3H, d, J 5), 2.65 (1H, double septuplet, J 4 and 7), 5.10 (1H, dd, J 10 and 4), \) and \(5.35 (1H, dq, J 10 \text{ and 5}).\)

**Purpose of the problem**

A simple way to make Z-alkenes, with a bit of NMR revision.

**Suggested solution**

This is obviously a Wittig reaction and we should expect a Z-alkene as the ylid is not stabilized by further conjugation. The evidence is plain: the signals at 5.10 and 5.35 are the alkene hydrogens and the coupling constant between them is 10 Hz. This is definitely a Z-alkene.
PROBLEM 6
A single geometrical isomer of an insect pheromone was prepared in the following way. Which isomer is formed and why?

Purpose of the problem
Testing your knowledge of the stereochemistry of the Wittig reaction.

Suggested solution
The first Wittig with a stabilized ylid gives the E-enal A. The second, with an unstabilized ylid, gives a Z-alkene so the final product is an E,Z-diene.
PROBLEM 7
How would you prepare samples of both geometrical isomers of this compound?

Purpose of the problem
A simple stereocontrolled alkene synthesis but both isomers are needed.

Suggested solution
There are many methods that can be used to tackle this question. The only snags are protecting the OH group if necessary and care in isolating the Z-compound as it may isomerize easily to the E-compound by reversible conjugate addition. One way to the Z-alkene uses reduction of an alkyne to control the stereochemistry. The OH group is protected as a benzyl ether removed by hydrogenation, perhaps under the same conditions as the reduction of the alkyne.

The E-alkene might be produced by reduction of the alkyne with an alkali metal in liquid ammonia but a Wittig reaction is probably easier. Either a phosphonium ylid or a phosphonate ester could be used. Protection of the alcohol as an ester allows hydrolysis of both esters in one step.
PROBLEM 8
Which alkene would be formed in each of these elimination reactions? Explain your answer mechanistically.

Purpose of the problem
Revision of the three main methods for stereoselective (or stereospecific) alkene bond formation.

Suggested solution
The first is sort of a Wittig reaction (the starting material is made by opening an epoxide with Ph₃P), the second a Julia reaction and the third and the fourth are Peterson reactions under different conditions. Each is described in detail in chapter 27 of the textbook. The Wittig reaction is under kinetic control and is a stereospecific cis elimination. In this case the product is a Z-alkene.

The Julia reaction is under thermodynamic control as equilibration occurs under the reaction conditions. The stereoselective product is the E-alkene.
The Peterson reaction is a syn-elimination under basic conditions, giving the Z-alkene from this starting material, but an E2 anti-elimination under acidic conditions, giving the E-alkene from this starting material.

PROBLEM 9

Give mechanisms for these reactions, explaining the role of silicon.

Purpose of the problem

Reminder of the anion-stabilizing role of sulfones and the excellence of the mesylate leaving group plus the special role of fluoride as a nucleophile for silicon.

Suggested solution

Sodium hydride removes a proton from the sulfone to give an anion that can act as a nucleophile. Displacement of mesylate gives an allyl silane, which is converted into an allylic anion by fluoride. Addition to the ketone gives a 5/5 fused system with the more stable cis ring junction.
PROBLEM 10

Give mechanisms for these reactions, explaining the role of silicon. Why is this type of lactone difficult to make by ordinary acid- or base-catalysed reactions?

Purpose of the problem

Basic organosilicon chemistry: the Peterson reaction and allyl silanes as nucleophiles.

Suggested solution

Acylation of the Grignard reagent is followed by a second attack on the ketone as expected but the tertiary alcohol is a Peterson intermediate and eliminates to give the alkene.

Now a Lewis acid catalysed reaction of the allyl silane via a $\beta$-silyl cation gives the lactone. The double bond in these ‘exo-methylene’ lactones easily moves into the ring in acid or base so mild conditions are ideal for these reactions.
PROBLEM 11
How would you carry out the first step in this sequence? Give a mechanism for the
second step and suggest an explanation for the stereochemistry. You may find
that a Newman projection helps.

Purpose of the problem
An important way to make an allyl silane and an important reaction of the
product.

Suggested solution
The best route to the allyl silane is the Wittig reaction (p. 675 of the
textbook). The ylid is not stabilized by extra conjugation so the Z-isomer is favoured.

The reaction with EtAlCl₂ is a Lewis acid-catalysed conjugate addition of
the allyl silane to the enone. Conjugate addition is preferred because the
nucleophile (the allyl silane) is tethered to the electrophile (enone) and the
five-membered ring is preferred to a seven-membered ring.

The stereochemistry comes from the way the molecule prefers to fold and
the Newman projection below should make that clear. The hydrogen atom
on the allyl silane tucks underneath the six-membered ring while the double bond of the allyl silane projects out into space to give the stereochemistry found in the product. The ratio between this diastereoisomer and the other varies from 2:1 to 7.5:1 depending on conditions so the preference is really quite weak.

PROBLEM 12
The following reaction between a phosphonium salt, base, and an aldehyde gives a hydrocarbon C₆H₁₂ with the 200 MHz 'H NMR spectrum shown. Give a structure for the product and comment on its stereochemistry.

Purpose of the problem
Confirming the stereochemistry of the product from a Wittig reaction.
Suggested solution

We'll approach this as a spectroscopic problem, rather than predicting the outcome and then making the data fit. First analyse the data, measuring chemical shifts, integrals and $J$ values.

From this alone we can see an alkene with two vicinal Hs, a methyl group, and an isopropyl group. That adds up to C$_6$H$_{12}$ so we have found everything and we can join it up in two ways as the alkene could be cis or trans. There is also a puzzle over the $J$ values—there are too many 5 Hz couplings and the second 10 Hz coupling is missing, but we'll unravel that later.

![Chemical structure](image)

The isopropyl group contains a 7 Hz coupling between the two methyl groups and the H at 2.70 ppm which is coupled to one of the alkene protons with $J = 4$ Hz. The remaining coupling of the alkene proton at 5.15 ppm (10 Hz) must be to the other alkene proton and that fits with a cis double bond. Working from the other end, the methyl group at 1.60 ppm is coupled to the alkene proton at 5.35 Hz with $J = 5$ Hz. Now we can solve the coupling constant mystery. We know that the alkene proton at 5.35 is actually a double quartet but it just so happens that the double coupling is exactly twice the quartet coupling. So we have two 1:3:3:1 quartets overlapping so that the inner lines coincide and give six lines in the ratio 1:3:4:4:3:1. The compound is cis (Z) 4-methylpent-2-ene. This is a Wittig reaction with an unstabilized ylid, so you should expect to find a cis double bond.
Suggested solutions for Chapter 28

PROBLEM 1
How would you make these four compounds? Give your disconnections, explain why you chose them and then give reagents for the synthesis.

Purpose of the problem
Exercises in basic one-group C–X disconnections.

Suggested solution
We wish to disconnect one of the C–N bonds and prefer the one not to the benzene ring as we aim to use reductive amination (p. 234 of the textbook) as the best way to make amines.

However the second aromatic amine can be made a different way. The two nitro groups promote nucleophilic aromatic substitution (p. 514 of the textbook) and the compound can be made by the addition-elimination mechanism from the dinitro chloro compound that can be made by direct nitration.
For the ether we again have a choice from two C–O disconnections. We prefer not to add the t-butyl group by SN2 (though we could by SN1) and disconnect on the other side. The synthesis is trivial: we just mix the two reagents with base or make the anion from the alcohol first.

For the sulfide we shall want to use an SN2 reaction and there is a slight preference for the disconnection we show as the allylic halide is very reactive. You would not be wrong if you had chosen the alternative C–S bond. This time only a weak base will be needed as the SH group is much more acidic than the OH group.

**PROBLEM 2**
How would you make these compounds? Give your disconnections, explain why you chose them and then give reagents for the synthesis.

**Purpose of the problem**
Exercises in basic one-group C–C disconnections.
Suggested solution

There are obviously more choices when you use C–C disconnections, but choose wisely! We suggest a solution, but you may have thought of others. The first compound is an alkyne and disconnection next to the alkyne (but not on the side of the benzene ring) makes a simple synthesis.

![Chemical structure and synthesis diagram]

The alcohol has some symmetry: you will want to use Grignard or organolithium chemistry (chapter 9) and you could disconnect one or two of the identical groups using a ketone or an ester as the electrophile. The double disconnection leads to a shorter synthesis.

![Chemical structure and synthesis diagram]

PROBLEM 3

Suggest ways to make these two compounds. Show your disconnections and make sure you number the functional group relationships.

![Chemical structures]

Purpose of the problem

First steps in using two functional groups to design a synthesis.
Suggested solution

Both compounds have two oxygens singly bonded to the same carbon atom: they are acetals so they come from a carbonyl compound. Disconnecting the acetals helps us see what we are really trying to make.

\[
\begin{align*}
\text{acetal} & \xrightarrow{1,1-\text{diX}} \text{1,1-diX} \\
\text{MeO} & \xrightarrow{1,1-\text{diX}} \text{CHO} + 2 \text{MeOH}
\end{align*}
\]

The diol has a 1,3-relationship between the two alcohols so we need aldol or Claisen ester chemistry (chapter 26). One alcohol will have to be changed into a carbonyl group, perhaps an aldehyde or ester. Since we shall reduce all carbonyl groups to alcohols, it doesn’t really matter whether we have aldehydes, ketones, or esters.

We prefer to make the disconnection between C2 and C3 to cut the molecule more or less in half and simplify the problem. There are various ways to do this—either the lithium or the zinc enolate would do, and below we show the use of zinc in a Reformatsky reaction.

If the keto-ester is used as a starting material it can be made by the same strategy (disconnection A) or alternatively (disconnection B) by first removing just one methyl group to reveal a symmetrical keto-ester made by a Claisen ester condensation.
Disconnection A

\[
\begin{align*}
\text{Disconnection B} & \\
\text{O} & \\
\text{CO}_2\text{Et} & \\
\text{O} & \\
\text{EtO} & \\
\text{CO}_2\text{Et} &
\end{align*}
\]

The advantage of disconnection B is that the synthesis involves a simple self-condensation of ethyl propionate. Methylation of the resulting keto-ester followed by reduction to the diol and acetal formation gives the target molecule.

\[
\begin{align*}
\text{O} & \\
\text{EtO} & \\
\text{CO}_2\text{Et} & \\
\text{O} & \\
\text{EtO} & \\
\text{CO}_2\text{Et} &
\end{align*}
\]

The other compound has a 1,5-relationship between the two functional groups and will need some sort of conjugate addition of an enolate (chapter 25). This time we want to reduce only one of the two carbonyl groups so we must make sure they are different. We already have an aldehyde so we choose an ester for the other one.

\[
\begin{align*}
\text{CHO} & \\
\text{R}_2\text{NH} & \\
\text{CHO} & \\
\text{CHO} &
\end{align*}
\]

We must use a specific enol equivalent for the aldehyde enolate to avoid self-condensation: an enamine or a silyl enol ether would be fine. Since we must reduce the ester in the presence of the aldehyde, it makes sense to put the acetal in before we do this.
PROBLEM 4
Propose syntheses of these two compounds, explaining your choice of reagents and how any selectivity is achieved.

Purpose of the problem
First steps in designing syntheses in which selectivity is required.

Suggested solution
The first compound is an α,β-unsaturated carbonyl compound and this is one of the most important functional group combinations for you to recognize in planning syntheses. It is the product of an aldol reaction so simply disconnect the alkene and write a new carbonyl group at the far end of the old one. Don't lose any carbon atoms!

We need a crossed aldol reaction between two ketones so we also need chemoselectivity. We have to make one enol(ate) from an unsymmetrical ketone so we need regioselectivity as well. The obvious solution is to use a lithium enolate, a silyl enol ether, or a β-ketoester. Here is one solution.

The second compound contains another common functional group: a lactone or cyclic ester. We should first disconnect the structural C-O bond to see the carbon skeleton.
We discover that we have a 1,5-relationship between the functional groups and so we shall need conjugate addition. We must change the alcohol into a ketone, and the acid group to an ester. Notice that there are two reasonable disconnections and that we have added an ester group to each potential enolate as the way of making a specific enolate.

One possibility is to add malonate to the unsaturated ketone, which is an aldol dimer of acetone and readily available. We can reduce the ketone, expecting cyclization to be spontaneous, and decarboxylate to give our target molecule.

- The strategy of using decarboxylation of a \( \beta \)-dicarbonyl compound is described on p. 597 of the textbook.
PROBLEM 5
The reactions to be discussed in this problem were planned to give syntheses of these three molecules.

In the event each reaction gave a different product from what was expected, as shown below. What went wrong? Suggest syntheses that would give the target molecules above.

Purpose of the problem
Finding out what might go wrong is an important part of planning a synthesis.

Suggested solution
The aldol reaction planned for target molecule 1 looks all right but enol formation has occurred on the wrong side. This is not surprising in acid solution, so use base instead.

In the second case, alkylation of the enolate of the ketone was planned but evidently it is easier to form the enolate of the chloro-ester. The reaction
that occurred is the Darzens condensation. To avoid this problem use a specific enolate of the ketone such as an enamine or a β-ketoester.

In the third case, the cyclopentanone has self-condensed and ignored the enone. The answer again is to use a specific enolate, such as the easily made β-keto-ester below. The six-membered ring is then easily formed by intramolecular aldol reaction. These two reactions together make a Robinson annelation. Finally the CO$_2$Me group must be removed by hydrolysis and decarboxylation.
PROBLEM 6
The natural product nuciferal was synthesized by the route summarized here.

(a) Suggest a synthesis of the starting material.
(b) Suggest reagents for each step.
(c) Draw the retrosynthetic analysis giving the disconnections that you consider the planners may have used and label them suitably.
(d) Which synthon does the starting material represent?

Purpose of the problem
Practice at an important skill—learning from published syntheses—as well as a popular style of exam question.

Suggested solution
(a) Grignard reagents are made from the corresponding halide and the rest of the analysis used simple C–X disconnections.

It turns out that the addition of HBr to the unsaturated aldehyde (trivially known as acrolein) and the protection as an acetal can be carried out in a single step as both are acid-catalysed.
(b) The Grignard has obviously been added to a ketone to give the tertiary alcohol, but how do we replace OH by H? One way is direct catalytic hydrogenation but an easier way is to eliminate the tertiary (and benzylic) alcohol and hydrogenate the alkene. The acid used for dehydration will also remove the acetal.

The last step is an aldol reaction between two aldehydes. The easiest way to do this is by a Wittig reaction but a specific enol of propanal would also be fine.

(c) and (d) The retrosynthetic analysis is straightforward except for the last step. It is not obvious what reagent to use for the synthon in brackets. But you already know what was used: a Grignard reagent with a protected aldehyde, i.e. a d₃ reagent. This is needed because the 1,4 relationship between OH and CHO requires *umpolung* (p. 720 of the textbook).
PROBLEM 7
Show how the relationship between the alkene and the carboxylic acid influences your suggestions for a synthesis of these three compounds.

Purpose of the problem
An exploration of the importance of functional group relationships.

Suggested solution
The first is an $\alpha,\beta$-unsaturated carbonyl compound and can best be made by an aldol reaction using some sort of specific enol equivalent for the acid part. A Wittig reagent, a malonate, or a silyl enol ether look the best.

The second synthesis is difficult because the alkene can easily slip into conjugation with the carbonyl group. Perhaps the easiest strategy is to use cyanide ion as synthetic equivalent of $-\text{CO}_2\text{H}$ since then the electrophile is an allylic halide. Other alternative routes could include alkyne reduction.

The third is best approached by alkylation of a malonate with allyl bromide itself followed by hydrolysis and decarboxylation.
Solutions for Chapter 28 – Retrosynthetic analysis

301

PROBLEM 8
How would you make these compounds?

Purpose of the problem
A reminder of reductive amination and that simple syntheses of apparently related compounds may require very different chemistry.

Suggested solution
The secondary amine is best made by reductive amination via the imine (not usually isolated).

The secondary alcohol can be made by some sort of Grignard chemistry. Cyclohexyl Grignard could be added twice to ethyl formate or once to the cyclohexane aldehyde.
The carboxylic acid could be made by double alkylation of malonate or some other specific enol equivalent.

Finally the primary amine could be made by reductive amination of a ketone that could in turn be made by oxidation of the secondary alcohol we have already made. Among many alternatives is the displacement of the tosylate of the same alcohol with azide ion and reduction of the azide.

**PROBLEM 9**
Show how the relationship between the two carbonyl groups influences your choice of disconnection when you design a synthesis for each of these ketones.
**Purpose of the problem**

An exercise in counting to reinforce the way that odd and even relationships affect the choice of a synthetic route.

**Suggested solution**

The three diketones have 1,3-, 1,4-, and 1,5-dicarbonyl relationships. In each case the obvious disconnection is of the bond joining the ring to the chain. But the chemistry is very different in each case. The 1,3-diketone can be made by acylation of a specific enolate. An enamine or a silyl enol ether is a good choice.

![1,3-diketone synthesis](image)

The same disconnection on the 1,4-diketone leads to different chemistry (alkylation of an enolate) and requires an enamine as the specific enol.

![1,4-diketone synthesis](image)

The 1,5-diketone requires conjugate addition of the same enolate and we suggest a different specific enolate equivalent though others would be just as good. This time the specific enol equivalent is needed to stop self-condensation of the cyclopentanone.

![1,5-diketone synthesis](image)
PROBLEM 10

A synthesis of this enantiomerically pure ant pheromone was required for the purposes of pest control. Given a supply of the enantiomerically pure alkyl bromide as a starting material, suggest a synthesis of the pheromone.

Purpose of the problem

Planning the strategy of a synthesis from a given starting material.

Suggested solution

We know what the disconnection must be, since we have been given one starting material. This looks like an enolate alkylation, and we need to use a specific enolate to stop the ketone self-condensing. The best enolate equivalent will be one that is not too basic, to avoid competing elimination. The simplest solution is probably to use a keto-ester, easily made by Claisen condensation with diethyl carbonate. After alkylation, the ester group is removed by decarboxylation.

Suggested solutions for Chapter 29

PROBLEM 1
For each of the following reactions (a) state what kind of substitution is suggested and (b) suggest what product might be formed if monosubstitution occurred.

\[
\begin{align*}
\text{N} & \quad \text{Br}_2 & \quad ? \\
\text{N} & \quad \text{HNO}_3 & \quad \text{H}_2\text{SO}_4 & \quad ? \\
\text{S} & \quad \text{MeCOCl} & \quad \text{SnCl}_4 & \quad ? \\
\text{F} & \quad \text{MeO}^\ominus & \quad ? \\
\end{align*}
\]

Purpose of the problem
A simple exercise in aromatic substitution on heterocycles.

Suggested solution
The first three reactions are all electrophilic substitutions: a bromination of a pyrrole, the nitration of quinoline, and a Friedel-Crafts reaction of thiophene. Bromination of the pyrrole occurs at the only remaining site. Nitration of quinoline occurs on the benzene rather than the pyridine ring (actually giving a mixture of 5- and 8-nitroquinolines) and the acylation occurs next to sulfur.

\[
\begin{align*}
\text{N} & \quad \text{Br}_2 & \quad \text{Br} \\
\text{S} & \quad \text{MeCOCl} & \quad \text{Me} \\
\text{F} & \quad \text{MeO}^\ominus & \quad ? \\
\end{align*}
\]

You needn't be concerned with the mixture of 5- and 8-nitroquinoline here, but p. 749 of the textbook has more detail.
The last reaction is a nucleophilic aromatic substitution on a pyridine. It occurs only at the site where the negative change in the intermediate can be delocalized onto the nitrogen.

![Reaction mechanism]

**PROBLEM 2**

Give a mechanism for this side-chain extension of a pyridine.

![Mechanism diagram]

**Purpose of the problem**

An exercise in thinking about the reactivity of alkylated pyridines.

**Suggested solution**

The strong base (LHMDS, lithium hexamethyldisilazide) removes a proton from the methyl group so that the anion is stabilized both by the nitrile and the pyridine nitrogen atom. Acylation occurs outside the ring to preserve the aromaticity. If you drew the lithium atom covalently bound to nitrogen, your answer is better than ours.

---

PROBLEM 3
Give a mechanism for this reaction, commenting on the position in the furan ring that reacts.

Purpose of the problem
An unusual electrophilic substitution on furan with interesting selectivity.

Suggested solution
Furans normally prefer substitution at the α-positions (2 or 5) but one α-position is already blocked and the other is too far away to reach the allyl cation. Attack at the other end of the allylic system would give an eight-membered ring with a trans alkene in it. This would theoretically be possible but closure of a six-membered ring is much faster. In other words, the electrophile and nucleophile are tethered.

PROBLEM 4
Suggest which product might be formed in these reactions and justify your choice.
**Purpose of the problem**
Regioselectivity test with contrasted electrophilic aromatic substitution.

**Suggested solution**
In each case we have a choice between reaction on a benzene ring or an aromatic heterocycle. The pyrrole is more reactive than the benzene and the pyridine less so. The pyrrole does a Vilsmeier reaction (p. 734 of the textbook) in the remaining free position while nitration occurs on the benzene. Pyridine acts as an electron-withdrawing and deactivating substituent, and therefore directs *meta*.

![Chemical structures](image1)

**PROBLEM 5**
Explain the formation of the product in this Friedel-Crafts alkylation of an indole.

![Chemical structures](image2)

**Purpose of the problem**
Checking up on your understanding of indole chemistry.

**Suggested solution**
The Lewis acid combines with allyl bromide to give either the allyl cation or the complex we show here. In either case, electrophilic attack occurs at the 3-position of the indole. The benzyl group migrates to the 2-position where there is a proton that can be lost to restore aromaticity.

![Chemical structures](image3)
PROBLEM 6
Suggest what the products of these nucleophilic substitutions might be.

\[
\begin{align*}
\text{NH}_2 \text{Me} \text{Cl} + \text{CO}_2\text{Et} & \rightarrow ? \\
\text{Cl} \text{N} \text{Cl} + \text{N} & \rightarrow ?
\end{align*}
\]

Purpose of the problem

Checking your understanding of nucleophilic aromatic substitution involving decisions on chemoselectivity and regioselectivity.

Suggested solution

Each compound has potential nucleophilic and electrophilic sites. In the first case the benzene ring is not activated towards nucleophilic substitution but the pyridine is, both by the pyridine nitrogen atom and by the ester group. The NH₂ on the benzene ring is much more nucleophilic than the pyridine nitrogen atom.

In the second case, the chlorine on the heterocyclic ring is much more reactive towards nucleophilic substitution as the intermediate is stabilized by two nitrogen atoms and the benzene ring is not disturbed. The saturated heterocycle (piperazine) can be made to react once only as the product under the reaction conditions is strictly the hydrochloride of the unreacted amino group. This is much more basic than the one that has reacted as that lone pair is conjugated with the heterocyclic ring.
PROBLEM 7
Suggest how 2-pyridone might be converted into the amine shown. This amine undergoes nitration to give compound A with the NMR spectrum given. What is the structure of A? Why is this isomer formed?

NMR of A: \( \delta_h: \) 1.0 (3H, t, \( J = 7 \text{ Hz} \)), 1.7 (2H, sextet, \( J = 7 \text{ Hz} \)), 3.3 (2H, t, \( J = 7 \text{ Hz} \)), 5.9 (1H, broad s), 6.4 (1H, d, \( J = 8 \text{ Hz} \)), 8.1 (1H, dd, \( J = 8 \text{ and } 2 \text{ Hz} \)), and 8.9 (1H, d, \( J = 2 \text{ Hz} \)).

Compound A was needed for conversion into the enzyme inhibitor below. How might this be achieved?

**Purpose of the problem**
Revision of proof of structure together with electrophilic and nucleophilic substitution on pyridines and a bit of synthesis.

**Suggested solution**
The first step requires nucleophilic substitution so we could convert the pyridine into 2-chloropyridine and displace the chlorine with the amine.
The nitration occurs only because this pyridine is activated by the extra amino group so you could start by predicting which compound might be made. Alternatively you could work out the structure from the NMR. The key points are (i) A has only three aromatic protons so nitration has occurred on the ring, (ii) there is only one coupling large enough to be between ortho hydrogens (8 Hz), and (iii) there is a proton that has only meta coupling (2 Hz) a long way downfield (at large chemical shift). The pyridine nitrogen causes large downfield shifts at positions 2, 4, and 6, the nitro group causes large downfield ortho shifts, and the amino group causes upward ortho shifts (to smaller δ). All this fits the structure and mechanism shown. The amino group directs ortho, para and para is preferred sterically.

To get the enzyme inhibitor we need to reduce the nitro group to an amine and add the new chain to the other amine. This conjugate addition is best done first while there is only one nucleophilic amine. The ester is probably the best derivative to use, but you may have chosen something else.
PROBLEM 8

The reactions outlined in the chart below were the early stages in a synthesis of an antiviral drug by the Parke-Davis company. Consider how the reactivity of imidazoles is illustrated in these reactions, which involve not only the skeleton of the molecule but also the reagent D. You will need to draw mechanisms for the reactions and explain how they are influenced by the heterocycles.

Purpose of the problem

An exploration of the chemistry of imidazole beyond that considered in chapter 29.

Suggested solution

The first reaction is the nitration of an imidazole in one of only two free positions. The position next to one nitrogen is more nucleophilic than the one between the two nitrogens. Imidazole has one pyridine-like and one pyrrole-like nitrogen so it is more nucleophilic than pyridine but less so than pyrrole.

The second reaction is like an aldol condensation between the methyl group on the ring and the benzaldehyde as the electrophile. The nitro group provides some stabilization for the ‘enolate’ but that would not be enough without the imidazole—ortho-nitro toluene would not do this reaction. The elimination is E1cB-like, going through a similar ‘enol’ intermediate.
Next, alkylation occurs on one of the nitrogen atoms in the imidazole ring. We need the anion of the imidazole which could be alkylated on either nitrogen. Alkylation on the lower N is preferred because the product has the longer conjugated system—we’ve put in the curly arrows to show it.

Ozonolysis of the alkene of C frees the carboxylic acid of D which reacts with carbonyl diimidazole E (CDI) in a nucleophilic substitution at the carbonyl group, with the relatively stable imidazole anion as the leaving group. The product is an ‘activated ester’, like an anhydride, from which the anion of nitromethane displaces the second molecule of imidazole to give the product F.

E = carbonyl diimidazole (CDI)

See pp. 622–3 of the textbook for some chemistry of the anion of nitromethane.
**PROBLEM 9**
What aromatic system might be based on this ring system? What sort of reactivity might it display?

![Pyrocoline structure]

**Purpose of the problem**
A chance for you to think creatively about aromatic heterocycles.

**Suggested solution**
The aromatic system has the poetic name 'pyrocoline' and you will have found it by trial and error. One ring looks like a pyridine and one like a pyrrole but counting the electrons should have made you realize that you need the lone pair on nitrogen to give a ten electron system. The nitrogen is therefore pyrrole-like and so if you predicted that this compound would react well in electrophilic substitutions on the five-membered ring you would be right: that is exactly what it does. The easiest pyrocolines to make have alkyl groups at position 3 and these compounds are nitrated to give the 4-nitro compounds. Friedel-Crafts reactions happen at the same atom.

![Pyrocoline reactions]

**PROBLEM 10**
Explain the order of events and the choice of bases in this sequence.

![Furan reaction sequence]

**Purpose of the problem**
The use of selective lithiation in furan chemistry.
**Suggested solution**

The allylic group evidently goes into the 2-position so deprotonation of the starting material by LDA must occur there, directed by both the oxygen and bromine atoms. The second electrophile (MeI) takes the place of the Br atom, so BuLi must lead to bromine-lithium exchange rather than deprotonation. The alternative order of events would require selective lithiation adjacent to the methyl group—not something you would expect to work reliably.

![Chemical structure diagram](image)

- Ortholithiation is introduced on pp. 563–4 of the textbook, and the lithiation of furan is on p. 737. Halogen-metal exchange is on p. 188.

This page intentionally left blank
Suggested solutions for Chapter 30

PROBLEM 1
Suggest a mechanism for this synthesis of a tricyclic aromatic heterocycle.

Purpose of the problem
A simple exercise in the synthesis of a pyridine fused to a pyrrole (or an indole with an extra nitrogen atom).

Suggested solution
The first step must be the formation of an enamine between the primary amine and the ketone. Now, because we have a pyridine and not a benzene ring, nucleophilic aromatic substitution can occur. These ‘aza-indoles’ are more easily formed than indoles.
PROBLEM 2
Is the heterocyclic ring created in this reaction aromatic? How does the reaction proceed? Comment on the regioselectivity of this cyclization.

Purpose of the problem
Exploring the synthesis and aromaticity of an unfamiliar heterocycle.

Suggested solution
The left-hand ring is obviously aromatic as it is a benzene ring. The right-hand ring has four electrons from the double bonds and can have two from a lone pair on oxygen, making six in all. This is more obvious in a delocalized form. Alternatively the whole system can be considered as a 10-electron molecule. Strangely enough, this is easier to see in the other Kekulé form.

The first step in the reaction is a transesterification and cyclization then occurs in the ortho position, para to the other hydroxyl group. Cyclization might have happened to the position in between the two substituents, as the other OH is ortho, para-directing, but the position chosen is more reactive for both steric and electronic reasons.
**PROBLEM 3**

Suggest mechanisms for this unusual indole synthesis. How does the second mechanism relate to electrophilic substitution on indoles (p. 746)?

**Purpose of the problem**

A combination of a Fischer indole synthesis with revision of a bit of indole chemistry from the last chapter.

**Suggested solution**

The first step starts off as a normal Fischer indole synthesis (we have omitted the first step); you just have to draw the molecules carefully to show the *spiro* ring system, and you have to stop before an indole is formed as the quaternary centre prevents aromatization.

Treatment with a Lewis acid initiates a rearrangement very like those occurring when 3-substituted indoles are attacked by electrophiles (p. 746 of the textbook). The aromatic ring is a better migrating group than the primary alkyl alternative and an indole can finally be formed.

PROBLEM 4

Explain the reactions in this partial synthesis of methoxatin, the coenzyme of bacteria living on methanol.

Purpose of the problem

A combination of Fischer indole synthesis with revision of indole chemistry from chapter 29.

Suggested solution

There is clearly a Fischer indole synthesis in the second step but the first step makes the usual hydrazone in a most unusual way. The first reaction is a diazotization so we have to combine the diazonium salt with the enolate of the keto-ester. That creates a quaternary centre and the KOH deacylates it to give the aryl hydrazone needed for the next step.
Now that we have the hydrazone, the Fischer indole step is straightforward and gives the indole-2-carboxylic acid derivative. There is only one site for an enamine and the indole is formed on the side of the benzene ring away from the other substituents.

The next stage must involve the primary amine as nucleophile and the conjugated keto-diester as electrophile. You may have expected direct addition of the amine to the ketone as that gives the product by a reasonable mechanism. In fact, conjugate addition must occur first as the tertiary alcohol A can be isolated. The dehydration is obviously acid-catalysed and the oxidation by air [or Ce(IV)] is also acid-catalysed.
**PROBLEM 5**

Explain why these two quinoline syntheses from the same starting materials give (mainly) different products.

![Chemical structures](image)

**Purpose of the problem**

An exercise in regioselectivity in a heterocyclic synthesis controlled by pH.

**Suggested solution**

You have a choice here: either you first form an enol(ate) from butanone and do an aldol reaction with the aromatic ketone or you first make an imine and then form enamines from that. In either case, you would expect enol or enamine formation on the more substituted side in acid but the less substituted side in base.
PROBLEM 6
Give mechanisms for these reactions used to prepare a fused pyridine. Why is it necessary to use a protecting group?

Purpose of the problem
Saturated and aromatic heterocycles combined with stereochemistry make an interesting synthesis for you to explore.

Suggested solution
The first starting material is a stable cyclic enamine and conjugate addition is what we should expect with an enone. Of course, if the aldehyde were unprotected, direct addition might occur there as well as carbonyl condensations. The product is in equilibrium with both its enols, one of which can cyclize to form the new six-membered ring.
The enol must attack the five-membered ring in a cis fashion as the tether is too short to reach the other side. There is no control over one stereogenic centre (represented with a wiggly line) but that is unimportant as it is soon to disappear.

Now the reaction with hydroxylamine in acid solution. Formation of the oxime of the ketone produces one molecule of water—just enough to hydrolyse the acetal—and the pyridine synthesis is completed by cyclization and a double dehydration (p. 765 of the textbook).

**PROBLEM 7**

Identify the intermediates and give mechanisms for the steps in this synthesis of a triazole.

\[
\begin{align*}
\text{O} & \overset{\text{cat.}}{\underset{\text{H}^+}{\longrightarrow}} \text{NH}_2 \\
\text{NH}_2 & \overset{\text{NaNO}_2, \text{HCl}}{\longrightarrow} \text{C}_2\text{H}_4\text{N}_2\text{O}_2 \\
\text{C}_2\text{H}_4\text{N}_2\text{O}_2 & \overset{\text{NaOAc, NaN}_3}{\longrightarrow} \text{C}_6\text{H}_2\text{N}_2\text{O}_2 \\
\text{C}_6\text{H}_2\text{N}_2\text{O}_2 & \overset{\text{HCl, EtOH}}{\underset{\text{reflux}}{\longrightarrow}} \text{C}_{16}\text{H}_{21}\text{N}_5\text{O}_3 \\
\text{C}_{16}\text{H}_{21}\text{N}_5\text{O}_3 & \overset{\text{1. HCl}}{\longrightarrow} \text{C}_{10}\text{H}_{17}\text{NO} \\
\text{C}_{10}\text{H}_{17}\text{NO} & \overset{\text{CHCl}_3}{\longrightarrow} \text{A} \\
\text{A} & \overset{\text{CHCl}_3}{\longrightarrow} \text{B} \\
\text{B} & \overset{\text{1. HCl, EtOH}}{\longrightarrow} \text{C} \\
\text{C} & \overset{\text{1. HCl, EtOH}}{\longrightarrow} \text{4-NO}_2\text{Ph} \\
\end{align*}
\]
Purpose of the problem

Revision of aromatic nucleophilic substitution and a chance to unravel an interesting mechanism.

Suggested solution

The first reaction forms A, just the enamine from the ketone and the secondary amine (morpholine). Below we have diazotization of an aromatic amine and replacement by azide to give B. This nucleophilic substitution could occur by the addition-elimination mechanism activated by the nitro group or by the S_N1 mechanism (chapter 22).

Now comes the interesting bit. The two reagents A and B combine without losing anything—it is evident that the enamine must be the nucleophile and so the azide must be the electrophile. We can see from the final product that the enamine attacks one end or the other of the azide. Trial and error takes over! Here is one possible solution with some side chains in the intermediate abbreviated for clarity. This product C can be isolated but its stereochemistry is not known.

Finally, the new aromatic system (a triazole) is formed by elimination of the aminal. Protonation of the most basic nitrogen is followed by expulsion of morpholine and aromatization by deprotonation.

An alternative is a 1,3-dipolar cycloaddition, see chapter 34.

This synthesis was discovered in Milan during a mechanistic study of the reactions between enamines and azides: R. Fusco et al., Gazz. Chim. Ital., 1961, 91, 849.
PROBLEM 8
Give detailed mechanisms for this pyridine synthesis.

Purpose of the problem
Revision of aldol and conjugate addition reactions of enol(ate)s and a synthesis involving two furans and one pyridine.

Suggested solution
The first reactions are an aldol condensation and a conjugate addition. We have shown just the first steps, but make sure that you can draw full mechanisms for both. The last step is a standard pyridine synthesis.
**PROBLEM 9**
Suggest a synthesis for this compound.

**Purpose of the problem**
The synthesis of an indole with a slight twist.

**Suggested solution**
This looks very much like a perfect subject for the Fischer indole synthesis. Let’s see.

This looks fine, though we may wonder how we are going to have an amino group in that position on the keto ester. Surely it will cyclize onto the ester to form a lactam? One solution would be to protect it with something like a Boc group, but the solution found by the Sterling drug company was partly motivated by a desire to make a variety of compounds with different amine substituents. They chose hydroxyl as an easily replaceable group and accepted that the starting material would exist as a lactone. They made it like this:

The first step is a typical Claisen ester condensation and the second is an acid-catalysed thermodynamically controlled transesterification (the lactone and ethyl ester exchange alcohol partners) to give the more stable six-membered lactone, followed by decarboxylation. Now the Fischer indole synthesis works well and work-up with dry HCl in methanol gave the alkyl
chloride that could be displaced with amines to give a series of anti-depressants.

PROBLEM 10
How would you synthesize these aromatic heterocycles?

Purpose of the problem
A chance to devise syntheses for five-membered aromatic heterocycles with one or two heteroatoms.

Suggested solution
These compounds all look much the same but the strategies needed for each are rather different. Removing the heteroatom from the thiophene reveals a 1,4-diketone to be made by one of the methods in chapter 28. We have chosen to propose an enamine and an \( \alpha \)-bromoketone though there are many other good choices.

The second compound is a thiazole and we want to use a thioamide to make it (see p. 771 of the textbook). We should disconnect C–N and C–S...
bonds to give the thioamide and another α-bromoketone remembering to let the nucleophiles exercise their natural preferences: sulfur attacking saturated carbon and nitrogen attacking the carbonyl group.

![Diagram of reaction](image1)

The third compound has the two heteroatoms joined together so we should keep them that way. We disconnect both C–N bonds revealing the hidden molecule of hydrazine (NH₂NH₂). We then need a 1,3-diketone so we need Claisen ester chemistry (chapter 26).

![Diagram of reaction](image2)
Suggested solutions for Chapter 31

PROBLEM 1
Predict the most favourable conformation for these insect pheromones.

Purpose of the problem
Practice at drawing the conformations of cyclic acetals.

Suggested solution
There are many good ways to draw these conformations and yet more not quite so good. The one thing you must do is place each acetal oxygen atom *axial* on the other ring to enjoy the full anomeric effect. We show three ways of drawing each compound. You get extra credit if you noticed that these compounds can each exist as two diastereoisomers and each diastereoisomer as two enantiomers.

The natural products are two compounds in the middle according to R. Baker *et al.*, *J. Chem. Soc.*, 1982, 601.
PROBLEM 2

The *Lolium* alkaloids have a striking saturated heterocyclic skeleton. One way to make this skeleton appears below. Suggest a mechanism and explain the stereochemistry.

![Chemical structure](image)

*Lolium* alkaloid skeleton

**Purpose of the problem**

Analysis of a reaction to make a bicyclic heterocycle stereospecifically.

**Suggested solution**

Bromine, of course, attacks the alkene to form a bromonium ion. If it has the right stereochemistry, it cyclizes but, if it doesn’t, it reverts to starting materials. The reaction may remind you of halolactonization (p. 568 of the textbook).

![Chemical structure](image)

This particular reaction was used by S. R. Wilson et al., *J. Org. Chem.*, 1981, **46**, 3887, to help establish the correct structure of the *Lolium* alkaloids.
**PROBLEM 3**

One of the sugar components of the antibiotic kijanimycin has the basic structure shown here and NMR spectrum given below. What is the stereochemistry? When you have deduced the structure, suggest which conformation the molecule will prefer.

![Chemical structure](image)

\[ \delta: 1.33 (3H, d, J 6 Hz), 1.61^* (1H, broad s), 1.87 (1H, ddd, J 14, 3, 3.5 Hz), 2.21 (1H, ddd, J 14, 3, 1.5 Hz), 2.87 (1H, dd, J 10, 3 Hz), 3.40 (3H, s), 3.99 (1H, dq, J 10, 3 Hz), 3.40 (3H, s), 1.33 (3H, d, J 6 Hz), 4.24 (1H, ddd, J 3, 3, 3.5 Hz) and 4.79 (1H, dd, J 3.5, 1.5 Hz). The signal marked * exchanges with D$_2$O.]

**Purpose of the problem**

Using NMR to deduce stereochemistry and seeing how stereoelectronics decide the conformation of a cyclic acetal.

**Suggested solution**

You can make some preliminary assignments from a combination of shift and coupling:

<table>

</tbody>
</table>

We don’t mind which is H\textsuperscript{2} or H\textsuperscript{3} as they don’t affect the stereochemistry, but we do mind which is H\textsuperscript{4} or H\textsuperscript{5}. Since H\textsuperscript{6} is a 10 Hz doublet coupled with H\textsuperscript{1}, we know that H\textsuperscript{1} is at 2.87 and is axial. This gives the entire assignment...
and the stereochemistry: H^5 and H^6 are axial; H^1 and H^4 are equatorial. That is why there are no large vicinal ($^3J$) couplings to the diastereotopic CH$_2$ group (H^2 and H^3). All couplings not shown on the second diagram are $<4$ Hz.

PROBLEM 4

Explain why this cyclization gives a preponderance (3:1) of the oxetane, though the tetrahydrofuran is much more stable.

Purpose of the problem

A reminder that Baldwin’s rules may apply to any cyclization.

Suggested solution

Clearly iodine attacks the alkene and the OH group adds to the intermediate iodonium ion. Let’s draw this first without stereochemistry to see what happens. The starting material is in the middle, with the pathway to the tetrahydrofuran (THF) running to the left and the oxetane to the right.

Whether the oxetane or the tetrahydrofuran is formed depends on which end of the iodonium ion is attacked by the OH group. In terms of Baldwin’s rules, oxetane formation is a simple 4-exo-tet reaction and is favoured. The THF formation is slightly more complicated. It is a 5-exo-tet as far as the SN$_2$ reaction is concerned, but in the transition state the nucleophile, the carbon atom under attack and the leaving group are also all in the same six-membered ring—there is disfavoured 6-endo-tet character. It is very difficult.
to get the two dotted lines in the transition state diagram at the required 180° to each other.

Now what about the stereochemistry? Did you notice that each product has an all-trans arrangement of substituents around the ring? And what about the second alkene? The two alkenes are in fact diastereotopic and which one is attacked by iodine as well as on which face determines the stereochemistry of the product. This is rather like iodolactonization. Iodine adds randomly and reversibly to both faces of both alkenes. Only when cyclization can give the most stable all-trans product does the reaction continue.

**PROBLEM 5**

Draw a mechanism for the following multistep reaction. Do the cyclization steps follow Baldwin’s rules?

**Purpose of the problem**

Baldwin’s rules at work in the synthesis of a bicyclic heterocycle with one nitrogen atom in both rings.

**Suggested solution**

Hydrolysis of the acetal releases an aldehyde and Mannich-style condensation leads to the product. The iminium ion forms by (favoured) 5-exo-trig attack on the aldehyde. The cyclization step in which the enol attacks the iminium ion is 6-endo-trig and is thus also favoured. By folding
This new synthesis of a bicyclic amine was reported by F. D. King, *Tetrahedron Lett.*, 1983, 24, 3281.

The molecule into a chair a reasonable overlap between the required p orbitals is possible.

![Diagram of molecular structures and reactions](image)

**PROBLEM 6**
Consider the question of Baldwin’s rules for each of these reactions. Why do you think they are both successful?

![Diagram of molecular structures and reactions](image)

**Purpose of the problem**
Developing judgement in using Baldwin’s rules in the synthesis of heterocyclic compounds.

**Suggested solution**
The first ring system is the same as the one we have just been considering but the route to it is decidedly different and is more demanding of Baldwin’s rules, though we should still describe it as 6-endo-trig. Manganese dioxide is a specific oxidant for allylic alcohols and conjugate addition of the amine to the enone gives the bicyclic amine. This works because *endo* reactions are just about all right when six-membered rings are formed and because conjugate addition is under thermodynamic control: as long as *some* of the reaction occurs, the product is the most stable compound in the mixture—any competing attack of the amine on the ketone gives a much less stable four-membered ring.

Solutions for Chapter 31 – Saturated heterocycles and stereoelectronics

The second example is again 6-endo-trig but it is acid-catalysed: protonation increases the reactivity of the enone and reduces its rigidity. Both these 6-endo-trig reactions occur through chair-like transition states rather like the example in the previous problem.

PROBLEM 7
A revision problem in spectroscopy. A Pacific sponge contains 2.8% dry weight of a sweet-smelling oil with the following spectroscopic details. What is its structure and stereochemistry?

Mass spectrum gives formula: C₉H₁₆O. IR 1680 and 1635 cm⁻¹.
δH 0.90 (6H, d, J 7), 1.00 (3H, t, J 7), 1.77 (1H, m), 2.09 (2H, t, J 7), 2.49 (2H, q, J 7), 5.99 (1H, d, J 16), and 6.71 (1H, dt, J 16, 7).
δC 8.15 (q), 22.5 (two qs), 28.3 (d), 33.1 (t), 42.0 (t), 131.8 (d), 144.9 (d), and 191.6 (s).

Purpose of the problem
A reminder of stereochemistry in two dimensions.

Suggested solution
The IR suggests a conjugated carbonyl compound, confirmed by the carbonyl and two alkene signals in the carbon NMR with the additional information that the carbonyl group is an aldehyde or ketone (δC about 200). The proton NMR shows it is a ketone (no CHO proton), that the alkene has two protons (5.99 and 6.71), and that they are trans (J = 16 Hz). We also see an ethyl group (2H q and 3H t) attached to something with no Hs (could it be the carbonyl group?). This suggests the unit in the margin which leaves only C₄H₈. We know we have Me₂CH- from the 6H d and that leaves only CH₂. We have a structure:

![Diagram of molecular structure]
PROBLEM 8

Reaction between this aldehyde and ketone in base gives a compound $A$ with the proton NMR spectrum: $\delta_H 1.10 \,(9H, \text{s}), 1.17 \,(9\text{H, s}), 6.4 \,(1\text{H, d, } J 15), \text{and } 7.0 \,(1\text{H, d, } J 15)$. What is its structure? (Don’t forget stereochemistry!). When this compound reacts with $\text{HBr}$ it gives compound $B$ with this NMR spectrum: $\delta_H 1.08 \,(9\text{H, s}), 1.13 \,(9\text{H, s}), 2.71 \,(1\text{H, dd, } J 1.9, 17.7), 3.25 \,(dd, \, J 10.0, 17.7), \text{and } 4.38 \,(1\text{H, dd, } J 1.9, 10.0)$. Suggest a structure, assign the spectrum, and give a mechanism for the formation of $B$.

Purpose of the problem

Slightly more difficult determination of stereochemistry moving from two to three dimensions. Revision of the Karplus relationship and of conjugate addition.

Suggested solution

The structure of $A$ is easy. It has a $\text{trans}$ alkene with two H’s ($J 15$) and two tertiary butyl groups. There isn’t much else except a carbonyl group so it must be an aldol product between the enolizable ketone and the unenolizable aldehyde.

$B$ is more difficult. The alkene has obviously gone (no signals beyond 4.48) and there is one extra H. It looks as though $\text{HBr}$ has added. The 17.7 coupling cannot be a $\text{trans}$ alkene as the chemical shifts are too small, so it must be geminal coupling. This means that the molecule must be chiral so
that the two hydrogens on the same carbon are diastereotopic. In fact, the expected conjugate addition of HBr to the enone has occurred.

\[ \text{HBr} \quad \text{A} \quad \text{OH} \quad \text{Br} \quad \text{O} \quad \text{Br} \quad \text{H} \quad \text{H} \quad \text{O} \quad \text{H} \quad \text{Br} \quad \text{H} \quad \text{H} \]

The three hydrogens that we have drawn form an ABX system: A and B are the diastereotopic CH\(_2\) group (\(J_{AB} = 17.7\)) and X is the CHBr proton (\(J_{AX} = 10\) and \(J_{BX} = 1.9\)). It is not normally possible to say which proton is A and which B but here the large groups, along with the big difference between the two coupling constants, allow us to surmise there is one favoured conformation with dihedral angles of about 180° and 60°.

\[ \text{favoured conformation has large groups anti-periplanar} \]

\[ \begin{align*}
2J & = 17.7 \text{ Hz} \\
3J & = 1.9 \text{ Hz}
\end{align*} \]

\(60^\circ\) angle \(180^\circ\) angle

**PROBLEM 9**

Two diastereoisomers of this cyclic keto-lactam have been prepared. The NMR spectra have many overlapping signals but the marked proton can be seen clearly. In isomer A it is at \(\delta = 4.12\) (1H, q, \(J = 3.5\)) and in isomer B it is \(\delta = 3.30\) (1H, dt, \(J = 4, 11\)). Which isomer has which stereochemistry?

**Purpose of the problem**

Assignment of three-dimensional stereochemistry from NMR when only one signal can be clearly seen.

Suggested solution

The two isomers have *cis* and *trans* ring junctions so we should start by making conformational drawings of both. The *trans* compound is easy as it has a fixed *trans*-decalin shape. The *cis* compound can have two conformations as both conformers can flip.

The vital proton is clearly axial in isomer B as it has two large couplings (10 Hz) to other axial protons so this must be the *trans* isomer. Isomer A has three equal small couplings and this fits one conformation of the *cis* isomer.

---

**PROBLEM 10**

Given a sample of each of these two compounds, how would you determine the stereochemistry?

---

**Purpose of the problem**

An approach from the other end: how would you do the job? Also to remind you that we can determine the *relative* stereochemistry (i.e. which diastereoisomer do we have?) but not the absolute stereochemistry (i.e. which enantiomer do we have?) by NMR.
Suggested solution

By NMR of course. Both compounds are six-membered rings so we should first make conformational diagrams of all the possibilities. Both will have the \( t \)-butyl group equatorial. The first compound can have the methyl group \( cis \) or \( trans \) to the \( t \)-butyl group while the second compound can have both methyl groups on the same side, on the other side to the \( t \)-butyl group, or one on each side. Two of these are \textit{meso} compounds though this doesn't affect the assignment.

The key H atoms in the NMR spectrum are those shown below. In the first compound \( H^D \) tells us nothing as it has no neighbours and no coupling. \( H^B \) and \( H^C \) are useful as they tell us about \( H^A \). \( H^A \) is easily identified by its quartet coupling to the methyl group. If it has a large axial-axial coupling (about 10 Hz) to \( H^B \) we have the \textit{cis} compound, but if all its couplings are small (perhaps \(< 4 \) Hz) then it is the \textit{trans} compound.

In the second compound a difficulty emerges: there is no coupling! We can tell by symmetry whether we have, on the one hand, the symmetrical \textit{cis}, \textit{cis}- or the \textit{trans}, \textit{trans}- compounds or, on the other hand, the non-symmetrical \textit{cis}, \textit{trans}- compound. The symmetrical compounds will of course show only one peak for the two methyl groups, for example. But how can we tell which of the symmetrical compounds we have? The chemical shifts will be different but we won't know which is which. However, if we irradiate the signal for the methyl groups, we should get a strong NOE (pp. 799–800 of the textbook) at \( H^A \) for the \textit{trans} compound and not for the \textit{all-cis} compound.
PROBLEM 11

The structure and stereochemistry of the antifungal antibiotic ambruticin was in part deduced from the NMR spectrum of this simple cyclopropane which forms part of its structure. Interpret the NMR and show how it gives definite information on the stereochemistry.

\[ \delta \text{H} 1.21 (3\text{H}, \text{d}, J 7 \text{Hz}), 1.29 (3\text{H}, \text{t}, J 9), 1.60 (1\text{H}, \text{t}, J 6), 1.77 (1\text{H}, \text{ddq}, J 13, 6, 7), 2.16 (1\text{H}, \text{dt}, J 6, 13), 4.18 (2\text{H}, \text{q}, J 9), 6.05 (1\text{H}, \text{d}, J 20), \text{and} 6.62 (1\text{H}, \text{dd}, J 20, 13). \]

**Purpose of the problem**

Assigning a more complex NMR and making decisions about stereochemistry in small rings.

**Suggested solution**

In cyclopropanes the cis coupling is usually larger than the trans coupling because the dihedral angle for cis Hs is 0° but that of trans Hs is not 180°.

Assigning the three ring hydrogens depends on (a) the quartet coupling to the methyl group, and (b) the 13 Hz coupling to the proton on the alkene. This means that the third proton on the ring (t, J 7) must be next to the carbonyl group. The two trans couplings round the ring are the same (6 Hz) and smaller than the cis coupling (7 Hz). The double bond geometry is on more certain grounds as 20 Hz can be only a trans coupling.
**PROBLEM 12**

A reaction produces two diastereoisomers of the product below: isomer A has δH 3.08 (1H, dt, J 4, 9, 9) and 4.32 (1H, d, J 9), while isomer B has δH 4.27 (1H, d, J 4). All other protons (except those of the Me groups) overlap in the NMR. Isomer B is converted into isomer A in base. What is the stereochemistry of A and B?

**Purpose of the problem**

Determining stereochemistry with the minimum of information.

**Suggested solution**

There are only two diastereoisomers and the difference in coupling constants is striking. The observed Hs must be those next to the functional groups. These compounds are not true cyclohexanes as they are flattened by the benzene ring and are best drawn as cyclohexenes. You should imagine the benzene ring coming towards you from the double bond.

The two protons we can see in isomer A must be H1 and H2 as they have the largest shifts. The proton with only one coupling must be H1 as it has only one neighbour H2. The coupling between these two is 9 Hz so they must both be axial. Isomer A is therefore the trans compound. H2 is a double triplet because it has two axial neighbours and one equatorial neighbour (H4). Isomer B shows H1 alone and it is clearly equatorial (J 4) and so it must be the cis isomer.

- A reminder: we are showing only relative configuration here; NMR tells us nothing about whether we have one or both enantiomers of each diastereoisomer.
Conversion to A occurs by enolate formation and the \textit{trans} compound is more stable than the \textit{cis}, as you might expect.

\textbf{PROBLEM 13}

Muscarine, the poisonous component of the death cap mushroom, has the structure below. We give the proton NMR spectrum. Can you see any definite evidence for the stereochemistry? Couplings are in Hz, m stands for multiplet, and * means that the proton exchanges with D$_2$O.

\begin{align*}
\delta & \quad 1.16 \ (3H, d, J \ 6.5), \ 1.86 \ (1H, ddd, J \ 12.5, 9.5, 9.5), \ 2.02 \ (1H, ddd, J \ 12.5, 6.0, 2.0), \\
& \quad 3.36 \ (9H, s), \ 3.54 \ (1H, dd, J \ 13, 9.0), \ 3.92 \ (1H, dq, J \ 2.5, 6.5), \ 4.03 \ (1H, m), \ 4.30^* \ (1H, d, J \ 3.5), \text{ and } 4.68 (1H, m).
\end{align*}

\begin{center}
\includegraphics{muscarine_structure}
\end{center}

\textbf{Purpose of the problem}

Demonstrating that it can be difficult to determine stereochemistry even with all the information.

\textbf{Suggested solution}

Couplings round five-membered rings tend to be much the same whether they are $^2J$ (geminal), $^3J_{\text{cis}}$ or $^3J_{\text{trans}}$ (vicinal). Even so, the two diastereotopic CH$_2$ groups are easy to find with their large $^2J$ couplings of 13 and 12.5 Hz. The one with extra coupling must be in the side chain and the other in the ring. Here is the full analysis. You will see that it is very difficult to get conclusive evidence on stereochemistry from NMR alone without using NOE. You should see that, in general, \textit{cis} couplings in five-membered rings tend to be larger than \textit{trans}, though there are many, many exceptions!

\begin{center}
\includegraphics{muscarine_analysis}
\end{center}

\hspace{1cm} The details are in J. Mulzer et al., \textit{Liebigs Ann. Chem.}, 1987, 7
PROBLEM 14
Treatment with base of the two compounds shown here gives an unknown compound with the spectra given below. What is its structure?

Treatment with base of the two compounds shown here gives an unknown compound with the spectra given below. What is its structure?

\[
\begin{align*}
\text{CHO} & + \text{Cl} \overset{\text{base}}{\longrightarrow} ? \\
\text{m/z: } 241 (M^+, 60\%), 90 (100\%), 89 (62\%) \\
\delta^H \text{ (ppm in CDCl}_3\text{): } 3.89 (1H, d, J 3 \text{ Hz}), 4.01 (1H, d, J 3 \text{ Hz}), 7.31 (5H, s), 7.54 (2H, d, J 10 \text{ Hz}) \text{ and } 8.29 (2H, d, J 10 \text{ Hz}) \\
\delta^C \text{ (ppm in CDCl}_3\text{): } 62, 64, 122, 125, 126, 127, 130, 136, \text{ and } 148 \text{ (the last three are weak).}
\end{align*}
\]

Purpose of the problem
Further practice at structure determination, making use of the size of the coupling constant.

Suggested solution
The compound is an epoxide: the coupling constants around the three-membered ring are small (3 Hz: contrast 10 Hz on the benzene ring) because of ring size and the oxygen atom. All the Hs on the Ph ring happen to come at the same chemical shift. Those on the nitrated ring are at lower field and separated by the nitro group.
This page intentionally left blank
Suggested solutions for Chapter 32

PROBLEM 1
Explain how the stereo- and regio-chemistry of these reactions are controlled. Why is the epoxidation only moderately diastereoselective, and why does the amine attack where it does?

Purpose of the problem
An exercise to remind you how important conformational analysis is in any stereoselective reactions of saturated six-membered rings.

Suggested solution
The conformation of the cyclohexene will place the ester group in an equatorial position, almost in the plane of the alkene, so that it offers only slight steric hindrance. The opening of the epoxide is dominated by conformation: approach a would give a twist-boat product but approach b gives the chair cyclohexane observed.

Before cyclization, the compound must go into a boat form so that the amine and the ester can approach one another. This boat is fixed in the final bicyclic structure. The cyclization does not affect the stereochemistry.
PROBLEM 2

Explain the stereochemistry of this sequence of reactions, noting the second step in particular.

Purpose of the problem

To show how even 'non-reactions' can influence stereochemistry.

Suggested solution

The hydrogenation will add a molecule of hydrogen in cis fashion to give what appears at first to be the wrong product.

The second step is important as it changes the stereochemistry. Ethoxide will form the enolate of the ester reversibly and allow it to move to the outside, convex face of the folded molecule. Though neutral nitrogen is not normally a chiral centre because it undergoes rapid pyramidal inversion, here it is fixed by the need of the 5/5 fused system to have a cis ring junction. The last step is just reduction of the ester with no change in stereochemistry.
PROBLEM 3

Comment on the control over stereochemistry achieved in this sequence.

Purpose of the problem

An exploration of stereochemistry in rings.

Suggested solution

The reducing agent could attack either side of the ring in the first step but by reacting with the OH group it can deliver hydride intramolecularly from the bottom face. The mesylation does not affect the stereochemistry as no bonds are formed or broken at any of the stereogenic centres.

The reaction with ammonia probably starts with displacement of the primary mesylate and the second displacement is intramolecular. It is also stereospecific as $S_N$2 reactions must occur with inversion and, fortunately, the amine is on the bottom face.

As described by E. J. Corey and group in *Tetrahedron Lett.*, 1979, 671.
PROBLEM 4
What controls the stereochemistry of this product? You are advised to draw the mechanism first and then consider the stereochemistry.

![Chemical structure]

**Purpose of the problem**

To show how ring-closing reactions, particularly those on the side of an already existing ring, can give excellent stereochemical control. And again, the importance of conformation in six-membered rings.

**Suggested solution**

We’d better draw the mechanism first, as the question suggests. Grignard reagents tend to do direct rather than conjugate addition to enones, and the product shows that the methyl group has done just that. But the OH group is in the wrong position to cyclize to the ester and there doesn’t seem to be much scope for stereochemical control so we probably get a mixture of diastereoisomers.

The first product is a tertiary allylic alcohol so it will lose water under the acidic work-up conditions to form a carbocation. Readdition of water to the other end of the allylic cation gives an alcohol that could cyclize to the final product.

An alternative and probably better mechanism is that the ester, or the acid derived from it by hydrolysis, cyclizes onto the allylic cation. In our first mechanism, the OH group would have to be on the same side of the ring as
the ester or acid to allow the lactone to form, but this cyclization gives the cis lactone directly from the allylic cation intermediate.

PROBLEM 5
Why is one of these esters more reactive than the other?

Purpose of the problem
Reminder of the power of folded molecules with concave and convex sides.

Suggested solution
The molecule is folded along the ring junction with one of the esters inside the fold (on the concave side) and one out in the open (on the convex side). In the rate-determining step of ester hydrolysis, the attack of the hydroxide ion on the carbonyl group, the forming tetrahedral intermediate is larger than the starting ester. This means that the ester on the outside, which has more room to 'expand', reacts faster than the ester on the inside.
Problem 6

Explain the stereoselectivity in these reactions.

Purpose of the problem

Another cyclization reaction and an example of a controlled inversion of configuration not using the $S_N2$ reaction.

Suggested solution

The first stereoselective reaction is surprising as it may appear that the initial alkylation decides the stereochemistry. But that is not the case as you will see if you draw the mechanism. The ester enolate is very easily formed as it is stabilized by the pyridine ring and the nitrile as well as by the ester. Even a weakish base such as carbonate is good enough.

The first intermediate produced by alkylation with the primary alkyl bromide (or the epoxide) has two stereogenic centres and will no doubt be formed as a mixture of diastereoisomers. But this doesn’t matter as the enolate has to be reformed for the next alkylation, and that destroys one of the chiral centres. We are back to a single compound again.
All now depends on the arrangement of the molecule for the cyclization step. The mechanism is straightforward enough but drawing the transition state is tricky. We offer two representations: an attempt at a conformational diagram and a Newman projection. The vital feature in both is that the enolate carbon and the C–O bond of the epoxide must be collinear. The molecule folds so that the five-membered ring bends upwards away from the large pyridine ring. This is not obvious even when you know the answer. You may have a better diagram.

The rest of the reactions are straightforward. Cyclization is spontaneous in base and the oxidation and reduction simply invert the OH group as the borohydride ion approaches the ketone from the side opposite the large pyridine ring.

PROBLEM 7
The synthesis of a starting material used in chapter 32 (p. 834 of the textbook) is a good example of how cyclic compounds can be used in a simple way to control stereo-chemistry. Draw mechanisms for each reaction and explain the stereochemistry.
**Purpose of the problem**

Reinforcement of material from chapter 32 and some important reactions.

**Suggested solution**

Tosylation of the primary alcohol is followed by ester exchange with methanol to release the anion of a secondary alcohol that promptly closes to an epoxide. There is no change at the stereogenic centre.

\[ 	ext{TsO} \rightarrow \text{K}_2\text{CO}_3 \rightarrow \text{MeOH} \rightarrow \text{CO}_2\text{Me} \]

Now the vinyl cuprate attacks the epoxide at its less substituted end, releasing the same oxyanion, which promptly closes the lactone again. Once more there is no change at the stereogenic centre.

\[ \text{CuR} \rightarrow \text{H}_2\text{O}_2 \rightarrow \text{Se} \text{Ph} \]

Finally, the double bond is introduced by selenium chemistry (p. 686 of the textbook). The steps are straightforward and the geometry of the alkene is dictated by the ring.
PROBLEM 8

Draw conformational drawings for these compounds. State in each case why the substituents have the positions you give. To what extent could you confirm your predictions experimentally?

Purpose of the problem

Further exploration of conformation and establishing the link with NMR spectra.

Suggested solution

The first two compounds have no choice about their conformation but the third does. The two functional groups prefer to be equatorial rather than axial.

Confirming the conformations experimentally means measuring coupling constants in the proton NMR so we need to look at the vital protons (marked ‘H’ in the diagrams below) and consider whether they can be seen in the spectrum. Fortunately the interesting protons are all next to functional groups so they will all be easily recognizable. We may find it difficult to identify the axial proton at the ring junction in the first example but trans decalins must have axial groups at the ring junction so that it not important.

In the first molecule, proton H has two neighbours, one axial (H⁺) and one equatorial (H⁻) so it will appear as a double doublet with characteristic large axial/axial and small axial/equatorial couplings. By contrast the two
marked equatorial Hs in the second compound have each got two axial and two equatorial neighbours and all the coupling constants will be about the same and small. They will both appear as narrow triplets of triplets but may be difficult to analyse. The important thing is that they have no large couplings. The two axial protons in the third example have each got two axial and two equatorial neighbours (one pair shown) and will again appear as triple triplets but this time one triplet will have a large axial/axial coupling.

**PROBLEM 9**
Predict which products would be formed on opening these epoxides with a nucleophile, say cyanide ion.

![Epoxide structures](image)

**Purpose of the problem**
Practice at choosing the correct regiochemistry of a stereoelectronically controlled epoxide opening.

**Suggested solution**
The opening of cyclohexene epoxides is controlled by the need to get the *trans* diaxial products. To get the right answer we need merely to draw the only possible *trans* diaxial (i.e. with CN and O– diaxial) product from each of these conformationally fixed *trans* decalins. Cyanide must, of course, open the epoxide with inversion so the OH group in the products is on the same side as the oxygen atom in the original epoxides.

![Reaction pathways](image)
PROBLEM 10
These two sugar analogues are part structures of two compounds used to treat poultry diseases. Which conformation will they prefer?

Purpose of the problem
Exploration of conformations in natural products with many substituents.

Suggested solution
Trial and error gives the conformation with the most equatorial substituents. The first compound can have all its substituents equatorial. The second can have three groups equatorial and one OH group axial, the preferred conformation due to the anomeric effect (pp. 801–3 of the textbook).

PROBLEM 11
Suggest a mechanism for the following reaction. The product has the following signals in its $^1$H NMR spectrum: $\delta$H 3.9 (1H, ddq, $J_{12, 4, 7}$) and 4.3 (1H, dd, $J_{11, 3}$). What is the stereochemistry and conformation of the product?

Purpose of the problem
A variation of a familiar mechanism, and illustration of how even limited spectroscopic data can help identify stereochemistry.
**Suggested solution**

The mechanism is formation of a bromonium ion by attack on the electron-rich alkene, followed by intramolecular nucleophilic attack by the OH group at the more substituted carbon atom. The NMR spectrum shows that the protons next to Br and O (shown as H^a and H^b) are both axial, since they have a large coupling constant of around 12 Hz (see pp. 796–9 of the textbook). The Br atom and the Me group must therefore be equatorial.

![Mechanism diagram](image)

**PROBLEM 12**

Revision problem. Give mechanisms for each step in this synthesis and explain any regio- or stereochemistry.

![Synthesis diagram](image)

**Purpose of the problem**

Revision of chapters 11 (acetal formation and hydrolysis) and 17 (eliminations) together with two reactions from this chapter: epoxidation and conformationally controlled opening of an epoxide on a six-membered ring.

**Suggested solution**

The first step is the standard formation of an acetal from a ketone. The epoxidation occurs from the bottom face of the ring (as drawn) because the axial methyl group blocks the top face. Ring opening with HF gives the trans di-axial product. The elimination is by the E1cB mechanism and the hydroxyl group is easily lost as it is axial.
This page intentionally left blank
Suggested solutions for Chapter 33

PROBLEM 1
How would you make each diastereoisomer of this product from the same alkene?

Purpose of the problem
A gentle introduction to stereochemical control in open-chain compounds.

Suggested solution
The compounds are acetals and can be made from the corresponding diols with no change in stereochemistry. The question really is: how do you make cis and trans diols from the alkene?

The cis diol is best made by dihydroxylation with OsO₄ as the reagent and a co-oxidant to regenerate it. The trans diol comes from the epoxide by nucleophilic attack with water.
**PROBLEM 2**

Explain the stereochemistry shown in this sequence of reactions.

\[
\begin{align*}
\text{1. } & 
\begin{array}{c}
\text{O} \\
\text{Zn(BH}_4\text{)}_2
\end{array} \\
& 
\begin{array}{c}
\text{CO}_2\text{Bn} \\
\text{OH}
\end{array}
\end{align*}
\]

Purpose of the problem

Chelation-controlled reduction is an important method for stereochemical control in open-chain compounds.

Suggested solution

In both reductions the zinc atom is coordinated to the oxygen of the nearer functional group (CO₂Bn in the first and OH in the second) and the oxygen of the ketone being reduced. This fixes the conformation of the molecule and the borohydride ion attacks from the less hindered side. *Anti* stereochemistry results in both cases.

---

You might prefer to draw the zinc-chelated structures as Newman projections, as shown in the textbook on p. 863.
PROBLEM 3
How is the relative stereochemistry of this product controlled? Why was this method chosen?

\[ \text{SO}_{2}\text{Ph} + \text{I} \rightarrow \text{OBn} \]

**Purpose of the problem**
This may seem trivial but the principle is important.

**Suggested solution**
The relationship between the two chiral centres in the product is 1,5 and that is too remote for any realistic control. The only plan is to disconnect between the two centres and add a removable anion-stabilizing group to one side and a leaving group to the other. The starting materials must of course be single enantiomers—then only one diastereoisomer can be formed.

\[ \text{OBn} \quad \text{OBn} \]

PROBLEM 4
When this hydroxy-ester is treated with a two-fold excess of LDA and then alkylated, one diastereoisomer of the product predominates. Why?

\[ \text{CO}_2\text{Et} + \text{Br} \rightarrow \text{OH} \]

**Purpose of the problem**
Analysis of an apparently simple case where chelation has the last word.
**Suggested solution**

The first LDA molecule removes the OH proton and only the second gives the lithium enolate. The enolate is held in a ring by chelation to the first lithium atom so that the allyl group adds to the less hindered face—opposite the methyl group. We’ve rotated the right hand end of the product to compare the stereochemistry clearly with the structure in the problem: make sure you can see that there is no change at the ester-bearing centre when you do this.

PROBLEM 5

Explain the stereochemical control in this reaction, drawing all the intermediates.

**Purpose of the problem**

Aldols are versatile and important ways of controlling open-chain stereochemistry by way of a cyclic transitions state.

**Suggested solution**

The geometry of the enolate is all important (p. 868 of the textbook) and here the large t-butyl group will direct the formation of the cis lithium enolate. Then the aldol reaction goes through a six-membered cyclic transition state (Zimmerman-Traxler) with the R group of the aldehyde taking up an equatorial position. This gives the syn aldol product.
PROBLEM 6
Explain how the stereochemistry of this epoxide is controlled.

Purpose of the problem
An example of the important iodolactonization reaction.

Suggested solution
The bicarbonate (NaHCO₃) is a strong enough base to remove the proton from the carboxylic acid. Iodine attacks the alkene reversibly to give a mixture of diastereoisomers of the iodonium ion. If the I⁻ and Me groups are on the same side of the chain, the carboxylate group can attack the iodonium ion from the back and set up a trans iodolactone. The iodolactone is cleaved by methoxide and the oxyanion displaces iodide to give the epoxide.
PROBLEM 7
Explain how these reactions give different isomers of the same product.

**Purpose of the problem**
Practice at analysing stereochemical control using the Felkin-Anh model.

**Suggested solution**
In each case we have nucleophilic attack on a carbonyl group with a neighbouring chiral centre. The Felkin-Anh analysis tells us first to put the largest group perpendicular to the carbonyl group and then to bring the nucleophile in alongside the smaller substituent. This is best shown as a Newman projection. In the first case it is better to rotate the front atom in the product so that the two Ph groups are at 180° and we can then draw the structure in the same arrangement.
PROBLEM 8

Explain the stereoselectivity of this reaction. What isomer of the epoxide would be produced by treatment of the product with base?

Purpose of the problem

A stereoelectronically controlled Felkin-Anh analysis.

Suggested solution

In this case the chloro substituent dominates because it has an electronic interaction with the carbonyl group. The two alkyl chains come out opposite one another so it is easy to draw the product in a reasonable fashion by imagining yourself observing the Newman projection from the top right.

To draw the stereochemistry of the epoxide formation it is sensible to put the reacting groups in the plane of the paper and arranged so that the oxyanion can do an $S_N^2$ displacement.
PROBLEM 9
How could this cyclic compound be used to produce the open-chain compound with correct relative stereochemistry?

Purpose of the problem
Practice at relating the stereochemistry of cyclic and open-chain compounds.

Suggested solution
We should first discover which atoms in the cyclic compound provide which atoms in the product. Numbering the atoms is the easiest way and it shows little change except that C9 has gone and C8 has become an aldehyde.

We need to hydrolyse the ester and the acetal and oxidize the 1,2-diol to cleave the C–C bond between the two OH groups. The stereochemistry at C3 and C7 is unchanged and neither is threatened by any of the reaction conditions.

---

Oxidative cleavage of diols is on p. 443 of the textbook.
**PROBLEM 10**
How would you transform this alkene stereoselectively into either of the diastereoisomers of the amino alcohol?

\[ \text{alkene} \rightarrow \text{OH} \quad \text{NH}\_2 \]

**Purpose of the problem**
A more difficult extension of problem 1.

**Suggested solution**
Opening the epoxide with a nitrogen nucleophile makes one isomer. At least the alkene is symmetrical so it doesn’t matter which end of the epoxide is attacked by the nucleophile. We have chosen azide ion as the nucleophile. You were not asked to make both diastereoisomers so we can stop there.

\[ \text{m-CPBA} \rightarrow \text{OH} \quad \text{NaN}_3 \rightarrow \text{OH} \quad \text{H}_2/\text{Pd/C} \rightarrow \text{NH}\_2 \]

**PROBLEM 11**
Explain the formation of essentially one stereoisomer in this reaction.

**Purpose of the problem**
A more difficult extension of problem 4 with added Felkin-Anh considerations.

**Suggested solution**
The \textit{syn} selectivity of the aldol reactions comes from the chair conformation of the cyclic (Zimmerman-Traxler) transition state. Ignoring the stereochemistry of the aldehyde we have this simplified explanation. The
transition state contains a chair in which the methyl group has no choice but to be axial while the aldehyde’s R substituent chooses to be equatorial.

We have inevitably drawn the syn aldol product as one enantiomer but so far we have no explanation for the control of absolute stereochemistry. The aldehyde itself is a single enantiomer so the two faces of the carbonyl group are diastereotopic and we might expect one would be chosen by the normal Felkin-Anh argument.

To our surprise this is not the preferred isomer. In fact the ‘anti-Felkin’ isomer predominates by about 3:1. The compound is entirely the syn aldol, as predicted, but attack has occurred on the aldehyde in the alternative conformation.

There is an important lesson to be learnt here. The principles we have been explaining are generally true but in any new individual case the result may not follow the principle. This is particularly true of Felkin-Anh control with aldehydes as the small size of the H atom allows other conformations to become relatively favourable.
PROBLEM 12
The following sequences show parts of the syntheses of two different HIV protease inhibitors. What reagents are required for steps 1–4? (For steps 1 and 3, consider carefully how the stereochemistry of the product might be controlled.)

Purpose of the problem
Choosing reagents to achieve desired stereo- and chemoselectivity.

Suggested solution
In step 1, we need to achieve diastereoselectivity during the addition of a nucleophile, CN–, to a carbonyl group adjacent to a stereogenic centre. The question is: do we need chelation control, or just Felkin-Anh control? Drawn out below is the conformation in which the aldehyde would react with cyanide if simple Felkin-Anh control were operating: check for yourself that the product is the correct one (you may need to build a model if you cannot see this easily). No chelation is needed. In step 2, the nitrile is hydrolysed to the acid and the benzyl groups are hydrogenolysed. This has to be the order; hydrogenolysis first risks reducing the nitrile to an amine.

In the second sequence, the nucleophile in step 3 must be a vinyl anion equivalent, maybe vinylmagnesium bromide. Comparison of the relative configuration of this product with the one above it immediately suggests that Felkin-Anh control is not operative here, since the opposite

In fact, this step was carried out with KCN in the presence of a Lewis acid (Me3Al) because the bulky benzyl groups prevent the nitrogen participating in chelation.
diastereoisomer is formed. Drawn below is the expected reactive conformation for a reaction involving chelation control: note that the acidic NH proton must be removed by any basic nucleophile. The outcome is correct: we need to achieve chelation control, so a magnesium counterion is a good choice (Mg$^{2+}$ readily takes part in chelated transition states). The final C=C bond cleavage in step 4 can be achieved by ozonolysis.

Methods for breaking a C=C bond to form a C=O bond are outlined on p. 443 of the textbook.
Suggested solutions for Chapter 34

**PROBLEM 1**
Predict the structure of the product of this Diels-Alder reaction.

```
  OMe  CO₂Me
Me₃SiO  +  ?  \[\text{[4 + 2]}\]
```

**Purpose of the problem**
Can you deal with a moderately complicated Diels-Alder?

**Suggested solution**
The diene is electron-rich and will use its HOMO in the cycloaddition. It will therefore prefer the alkene with the lowest LUMO and that must be the unsaturated ester. Both substituents on the diene direct reaction to the same end. We can predict this from electron donation from either of the oxygen atoms of the diene and in other ways.

The stereochemistry of the alkene (H and CO₂Me *cis*) will be faithfully reproduced in the product. The stereochemistry at the OMe group comes from *endo* attack—we should tuck the ester group underneath (or above—makes no difference) the diene so that it can overlap with the orbitals of the middle two atoms of the diene. If you also said that this product would eliminate methanol on workup so that only the stereochemistry of the ring junction matters, you’d be right.

\[\text{This chemistry is part of a synthesis of the antitumour agent vernolepin by S. Danishefsky and group, J. Am. Chem. Soc., 1976, 98, 3028.}\]
PROBLEM 2
Comment on the difference in rate between these two reactions.

Purpose of the problem
More details of the intramolecular Diels-Alder reaction.

Suggested solution
The dienes are the same, the ring sizes are the same, and the only difference is the presence of a benzene ring in the faster reacting compound. We should draw a mechanism for one of the reactions to see what is happening.

We are making two new rings. The six-membered ring containing an alkene in the product presents no problem. The eight-membered ring with a ketone in it might present a problem, but the ten-membered ring containing a trans alkene is definitely a problem. It is much easier to make medium rings (8- to 14-membered) when there is a cis alkene in the ring and the benzene ring helps there. It also increases the population of conformers with
the ends of their chains close together and probably lowers the LUMO energy by conjugation with the ketone.

**PROBLEM 3**
Justify the stereoselectivity in this intramolecular Diels-Alder reaction.

**Purpose of the problem**
Exploring the stereochemistry of an intramolecular Diels-Alder reaction.

**Suggested solution**
Intramolecular Diels-Alder reactions can give *endo* - or *exo* - products. We should first discover which this is. Drawing the transition state for the *endo* reaction, we find that it is correct—the *endo* product is formed. So electronic factors dominate, perhaps because the dienophile has such a low-energy LUMO and it has two carbonyl groups for secondary orbital overlap with the back of the diene.

PROBLEM 4
Explain the formation of single adducts in these reactions.

Purpose of the problem
Investigating the regio- and stereoselectivity of one inter- and one intramolecular Diels-Alder reaction.

Suggested solution
The stereochemistry of the first reaction is straightforward: it gives the endo product.

The regiochemistry is not quite so simple. The diene has the larger HOMO coefficient at the top end as drawn, so we must deduce that the largest LUMO coefficient in the unsymmetrical quinone is at the top left as drawn. This would result from the electron-donating MeO group making the top carbonyl group and the right-hand alkene less electrophilic, while the bottom carbonyl activates the top end of the left-hand alkene. Or, if you use the mnemonic, this is an ‘ortho’ product.
The second example is intramolecular so the regiochemistry is determined by that alone: the ester linkage between the diene and the dienophile is too short for any variation. This same link ('tether') also forces the dienophile to approach the diene from below. All that remains is the endo/exo question and the diagram shows that the product is endo with the carbonyl group tucked under the back of the diene.

**PROBLEM 5**

Suggest two syntheses of this spirocyclic ketone from the starting materials shown. Neither starting material is available.

**Purpose of the problem**

Revision of synthesis (chapters 24 and 28) with some cycloaddition. Helping you to see that there are alternative ways of making six-membered rings.

**Suggested solution**

The most obvious disconnection is of the α,β-unsaturated ketone with an aldol reaction in mind. This reveals a 1,4-dicarbonyl compound. Direct disconnection to one of the starting materials is now possible and each can be made by a Diels-Alder reaction.
The Diels-Alder reaction has the right (‘para’) regioselectivity, especially if we use a Lewis acid catalyst such as SnCl₄, and we shall need a non-basic specific enol equivalent for the alkylation: an enamine will do fine.

The other route demands a different disconnection of the keto-aldehyde plus one further aldol disconnection. The starting material is more easily made by Birch reduction than by a Diels-Alder reaction.

The Birch reduction gives the enol ether of the ketone and demands careful hydrolysis to avoid the alkene moving into conjugation with the ketone. The aldol reaction requires some kind of control—perhaps the silyl enol ether of acetone will do. Now we need a reagent for ‘–CHO’ that will do conjugate addition. The most obvious choices are cyanide ion or nitromethane. The last step is the same as in the first synthesis.
**PROBLEM 6**

Draw mechanisms for these reactions and explain the stereochemistry.

\[
\text{1. Ph} \quad \xrightarrow{\text{N-O}} \quad \text{2. LiAlH}_4
\]

**Purpose of the problem**

Exploration of stereochemical control by 1,3-dipolar cycloaddition reactions. Revision of the importance of cyclic compounds in stereochemistry.

**Suggested solution**

The nitrile oxide adds in one step to the cis alkene to give a single diastereoisomer of the 1,3-dipolar cycloadduct. This is a [3+2] cycloaddition with the three-carbon dipole supplying four electrons. The two methyl groups on the alkene start cis and remain so in the adduct.

The first reduction must be of the imine as it is stereoselective, with hydride being transferred to the face of the five-membered ring opposite to the methyl groups. N–O reduction follows.

If reduction of the N–O bond occurred first, we should expect little control in the reduction of the open chain imine.
PROBLEM 7
Give mechanisms for these reactions and explain the regio- and stereochemical control (or lack of it!). Note that MnO₂ oxidizes allylic alcohols to enones.

Purpose of the problem
Selectivity and application of a 1,3-dipolar cycloaddition.

Suggested solution
The first thing to do is to sort out the mechanism for the cycloaddition. The nitrone uses its LUMO (the \(\pi^*\) of the C=N bond) to react with the HOMO of the diene whose largest coefficient is at the end away from the phenyl group (this is where an electrophile would react). There is no selectivity as there is no conjugation and no \(exo/endo\) selection.

Reduction with zinc cleaves the N–O bond and MnO₂ oxidizes the allylic alcohol to the enone. At this point there is only one chiral centre so the mixture of diastereoisomers has become one compound. Conjugate addition of the amine gives the new ring.

The stereochemistry is more difficult to explain. The product will choose a \(trans\) ring junction (the nitrogen can invert and \(trans\) 6,6-ring fusions are

The 1,3-dipolar cycloaddition was developed by J. J. Tufariello and R. G. Gatrone, *Tetrahedron Lett.*, 1978, 2753.
more stable), but that means the phenyl group has to be axial, which is presumably not the more stable arrangement. It seems likely that this is the kinetic product. It looks as though the ring closes with the best overlap between the nitrogen lone pair and the $\pi^*$ orbital of the enone to give a cis ring junction that equilibrates by pyramidal inversion at nitrogen to the more stable trans ring junction. Axial phenyl is not so bad here as there is only one 1,3-diaxial interaction to the phenyl group, and even that is just with a hydrogen atom.

![Chemical structure](image1.png)

**PROBLEM 8**

Suggest a mechanism for this reaction and explain the stereo- and regiochemistry.

![Chemical structure](image2.png)

**Purpose of the problem**

Two non-routine Diels-Alder-type reactions.

**Suggested solution**

The reaction is clearly a cycloaddition but at first sight the selectivity is all wrong. The puzzle is solved when we realize that this is a reverse electron demand Diels-Alder. The diene is very electron-deficient with its two conjugated carbonyl groups so the dienophile needs to be electron-rich. It is not very electron rich as drawn, but its enol is. The first formed adduct loses carbon dioxide in a reverse cycloaddition.

![Chemical structure](image3.png)
PROBLEM 9
Photochemical cycloaddition of these two compounds is claimed to give the
diastereoisomer shown. The chemists who did this work claimed that the
stereochemistry of the adduct is simply proved by its conversion into a lactone on
reduction. Comment on the validity of this deduction and explain the
stereochemistry of the cycloaddition.

Purpose of the problem

Suggested solution
Either of the two starting materials could absorb the light to provide the
SOMO for the cycloaddition. This does not affect the stereochemistry of the
reaction. There is no \textit{endo} effect in [2 + 2] photocycloadditions so the
molecules simply come together with the rings arranged in an \textit{exo} fashion to
give the least steric hindrance.

The stereochemistry is easy to explain as the molecule is folded in such a
way that only the bottom face of the carbonyl group is open to nucleophilic
attack. The oxyanion produced can immediately cyclize to form the lactone.
Clearly this is possible only if the O\textsuperscript{−} group is up but also only if the CO\textsubscript{2}Me
groups are on the same side of the middle four-membered ring as the O\textsuperscript{−}
group. The formation of the lactone does indeed prove the stereochemistry.
Thioketones, with a C=S bond, are not usually stable. However, this thioketone is quite stable and undergoes reaction with maleic anhydride to give an addition product. Comment on the stability of the thioketone, the mechanism of the reaction, and the stereochemistry of the product.

Purpose of the problem

Exploration of a new structure, revision of aromaticity, and an encounter with [8 + 2] cycloadditions.

Suggested solution

This particular thioketone is stable because the C=S bond is very polarized by delocalization making the seven-membered ring an aromatic cation with six electrons in it. You can represent this in various ways.

The cycloaddition uses maleic anhydride as a two-electron component with a low LUMO. Although in principle this could undergo a Diels-Alder reaction with one of the dienes in the thioketone, it prefers to react by including the sulfur atom, using eight electrons in a component with a high HOMO coefficient. The tricyclic product is clearly folded back on itself so that the triene in the seven-membered ring and the carbonyl groups in the anhydride are close to each other. From the outcome, it seems there must be an endo effect in this [8 + 2] cycloaddition.
PROBLEM 11

This unsaturated alcohol is perfectly stable until it is oxidized with Cr(VI): it then cyclizes to the product shown. Explain.

Purpose of the problem

Discovery of a common effect in intramolecular cycloadditions.

Suggested solution

The starting material might undergo a Diels-Alder reaction but the diene and the dienophile are poorly matched. Both have high energy HOMOs and there isn’t a low energy LUMO in sight. Once the enone is formed, the alkene becomes electron-deficient: now the energies match well and cycloaddition is fast. The stereochemistry comes from an endo arrangement.
PROBLEM 12
Give mechanisms for these reactions, explaining the stereochemistry.

Purpose of the problem
Looking at [2 + 2] cycloadditions of ketenes.

Suggested solution
Treatment of acid chlorides with tertiary amines produces ketenes. In this case an intramolecular [2 + 2] cycloaddition is possible. The stereochemistry is trivial: a cis ring junction is the only one possible.

If a more reactive alkene (in this case the electron-donating O makes the enol ether more reactive) is available, the ketene adds to that instead. Note that the alkene must be present as the ketene is generated. The mechanism and part of the stereochemistry are simple. Because the cyclic alkene has cis stereochemistry, the two hydrogens on the six-membered ring must be cis in the product. The regiochemistry arises because the alkene is an enol ether and the large coefficient in its HOMO interacts with the central atom of the ketene, the one with the larger LUMO coefficient.
The stereochemistry at the remaining centre comes from the way the two molecules approach one another. The two components are orthogonal and the dotted lines in the middle diagram below show how the new bonds are formed. The carbonyl group of the ketene will prefer to be in the middle of the ring and the side chain of the ketene will bend down away from the top ring. These [2 + 2] thermal cycloadditions normally give an all cis product.

Suggested solutions for Chapter 35

PROBLEM 1
Give mechanisms for these steps, commenting on the regioselectivity of the pericyclic step and the different regioselectivity of the two metals.

![Mechanisms](image)

Purpose of the problem
A gentle introduction to an electrocyclic reaction without stereoselectivity.

Suggested solution
Grignard reagents generally prefer direct to conjugate addition, especially with unsaturated aldehydes. MnO₂ specializes in oxidizing allylic alcohols and is the gentle oxidant we need to produce the unstable enone.

![Mechanisms](image)

The pericyclic process comes next and it is a Nazarov reaction (p. 927 of the textbook), a conrotatory electrocyclic closure of a pentadienyl cation to give a cyclopentenyl cation. There is no stereochemistry and the only regiochemistry is the position of the alkene at the end of the reaction. It prefers the more substituted side of the ring.

![Mechanisms](image)
The final cuprate addition goes in a conjugate fashion as we should expect as this is what Cu(I) cuprates do. The cis 5,5 ring junction is much preferred to trans and can equilibrate on work-up by enolization.

**PROBLEM 2**

Predict the product of this reaction.

**Purpose of the problem**

A gentle introduction to a sigmatropic reaction without stereo- or regioselectivity.

**Suggested solution**

This is a classic Claisen [3,3]-sigmatropic rearrangement sequence starting with an allylic alcohol and forming a vinyl ether by acetal (or in this case orthoester) exchange. The reaction is very trans selective.

This product was used in a synthesis of chrysanthemic acid by Jacqueline Ficini and Jean d'Angelo: *Tetrahedron Lett.*, 1976, 2441.
PROBLEM 3
Give mechanisms for this alternative synthesis of two fused five-membered rings.

Purpose of the problem
Exploring another aspect of the Nazarov cyclization.

Suggested solution
The first stage is an aliphatic Friedel-Crafts reaction with an acylium ion attacking the alkene.

Next, a Nazarov reaction catalysed by a different Lewis acid closes the five-membered ring and puts the alkene in the only place it can go. The electrocyclic step is conrotatory but that has no meaning with this achiral product.

PROBLEM 4
Explain what is going on here.

Purpose of the problem
Two pericyclic reactions: a sigmatropic shift and a cycloaddition in one reaction scheme.

Suggested solution
The aromatic anion of cyclopentenone displaces tosylate from the alkyl group and then a [1,5] hydrogen shift gives the first product. Such a shift is allowed suprafacially on the ring.

Now there is an intramolecular Diels-Alder reaction requiring a high temperature because the dienophile is not activated. The stereochemistry is not obvious but there is no endo effect so the molecule folds to give the new five-membered ring a cis junction with the old.

**PROBLEM 5**

A tricyclic hydroxyketone was made by hydrolysis of a bis silyl ether. Further reaction gave a new compound. Explain these reactions including the stereochemistry. The diene has the proton NMR spectrum: $\delta = 6.06$ (1H, dd, $J = 10.3, 12.1$), $6.23$ (1H, dd, $J = 10.3, 14.7$), $6.31$ (1H, d, $J = 14.7$), and $7.32$ (1H, d, $J = 12.1$). Does this agree with the structure given?

**Purpose of the problem**

Relating the material of this chapter to that of previous chapters with some revision of basic mechanisms.

**Suggested solution**

The first sequence of reactions is simple. Protonation of the enol ether occurs on the convex face so the OH group is pushed into the endo side. Hydrolysis gives the hydroxy-ketone and the tosylate.

The tosylate is displaced with inversion by the excellent $S_n2$ nucleophile PhS$^-$ and reduction of the ketone from the exo face followed by acetylation gives the key intermediate.
Heating this product leads to a retro Diels-Alder reaction: cyclopentadiene is released and a cyclobutene is formed stereospecifically \textit{trans}. This now decomposes by a four-electron conrotatory electrocyclic reaction that could give either the \textit{E,E}- or the \textit{Z,Z}- diene.

The NMR spectrum clearly shows that the \textit{E,E}-diene is formed. The coupling constants for the simple doublets must be for the terminal hydrogens and 14.7 Hz is definitely a \textit{trans} coupling. You might think 12.1 is a bit small for the other \textit{trans} coupling as it is on the low side but the alkene has an electronegative substituent (OAc) and this reduces $J$.

\begin{itemize}
\item It's worth noting for future reference that enol ethers (and enol esters) often have surprisingly small alkene coupling constants.
\end{itemize}

\textbf{PROBLEM 6}

Treatment of this imine with base followed by an acidic work-up gives a cyclic product with two phenyl groups \textit{cis} to one another. Why is this?

\textbf{Purpose of the problem}

An unusual example of an electrocyclic reaction on an anion.

\textbf{Suggested solution}

The proton from the middle of the molecule is removed to give an anion stabilized by two nitrogens and three phenyl groups. A six-electron
electrocyclic reaction closes the five-membered ring and this must be disrotatory, moving both phenyl groups up (or down).

PROBLEM 7
This problem concerns the structure and chemistry of an unsaturated nine-membered ring. Comment on the structure. Explain its different behaviour under thermal or photochemical conditions.

Purpose of the problem
Revision of aromaticity and two alternative electrocyclic reactions.

Suggested solution
The amine has eight electrons in alkenes and two on the nitrogen atom making ten in all. It could be aromatic with $4n + 2$ electrons ($n = 2$). The two reactions are clearly electrocyclic and must be disrotatory to get cis ring junctions, the only possible arrangement for two flat rings. Thermally this means a six electron process, but photochemically an eight electron process is all right. The nitrogen does not appear to be involved in either reaction.

This was an investigation into the aromaticity of the starting material by A. G. Anastassiou and J. H. Gebran, *Tetrahedron Lett.*, 1969, 5239.
PROBLEM 8
Propose a mechanism for this reaction that accounts for the stereochemistry of the product.

\[
\begin{align*}
\text{Ph} & \quad \text{EtO}_2\text{C} & \quad \text{heat} \\
\text{Ph} & \quad \text{H} & \\
\text{Ph} & \quad \text{Ph} & \\
\text{N} & \quad \text{EtO}_2\text{C} & \\
\text{Ph} & \quad \text{Ph} & \\
\text{Ph} & \quad \text{Ph} \\
\text{N} & \quad \text{EtO}_2\text{C} & \\
\text{Ph} & \quad \text{Ph} & \\
\end{align*}
\]

Purpose of the problem
Another electrocyclic/cycloaddition combination for you to work out.

Suggested solution
The three-membered ring opens using the lone pair on nitrogen in a four-electron conrotatory electrocyclic process. One phenyl group must rotate inwards and the other outwards. Then a cycloaddition of the four-electron 1,3-dipole onto the two-electron dienophile goes without change of stereochemistry. The ester groups remain \( \text{cis} \) and the phenyls must be one up and one down.

PROBLEM 9
Treatment of this amine with base at low temperature gives an unstable anion that isomerizes to another anion above \(-35 ^\circ\text{C}\). Aqueous work-up gives a bicyclic amine. What are the two anions? Explain the stereochemistry of the product. In the NMR spectrum of the product the two protons in the grey box appear as an ABX system with \( J_{AX} 15.4 \text{ Hz} \). Comment.

Purpose of the problem

An unusual electrocyclic reaction on an anion with stereochemistry and NMR revision.

Suggested solution

The first anion A is formed by removal of the only possible proton: one from the NCH$_2$ group. This anion might be considered aromatic (six electrons from the three alkenes, two from N and two from the anion) but it is clearly unstable as it closes in an electrocyclic reaction at $> -35 \ ^\circ\text{C}$. This is a six-electron process and must therefore be disrotatory. The rotating hydrogens are shown on the structure of A. It is essential that the 5,5 ring closure must be cis and that demands a disrotatory reaction. Both anions A and B are extensively delocalized and it is a matter of choice where you draw the anion.

Anion B is protonated by water with preservation of the right hand aromatic ring. The final product is a chiral molecule having no plane of symmetry so the boxed CH$_2$ group is diastereotopic with $J_{AB}$ 15.4 Hz. This is larger than usual because of the $\pi$-contribution: a neighbouring $\pi$-bond increases $J$ by about 2 Hz.

---

This study was originally aimed at finding out the nature of the starting material, A. G. Anastassiou and group, *J. Chem. Soc., Chem. Commun.*, 1981, 647.
PROBLEM 10
How would you make the starting material for these reactions? Treatment of the anhydride with butanol gives an ester that in turn gives two inseparable compounds on heating. On treatment with an amine, an easily separable mixture of an acidic and a neutral compound is formed. What are the components of the first mixture and how are they formed?

Purpose of the problem
Exploration of alternative conrotatory openings of a cyclobutene.

Suggested solution
The starting material is made by a photochemical [2 + 2] cycloaddition of acetylene and maleic anhydride. Treatment with butanol and base gives the monoester because, after butanol has attacked once, the product is the anion of a carboxylic acid and cannot be attacked again by the nucleophile.

Heat opens the cyclobutene in a conrotatory four-electron electrocyclic reaction. As the two groups are cis on the cyclobutene, one must rotate outwards and one inwards. The two groups are similar but not the same so there is little selection and both products are formed.
Treatment with the tertiary amine forms the anions of the carboxylic acids. The one from B can do a conjugate addition to the unsaturated ester and form a lactone but that of A is too far away and cannot react.

![Chemical structure image]

**PROBLEM 11**

Treatment of this keto-aldehyde (which exists largely as an enol) with the oxidizing agent DDQ (a quinone—see p. 764 of the textbook) gives an unstable compound that turns into the product shown. Explain the reactions and comment on the stereochemistry.

![Chemical structure image]

**Purpose of the problem**

Exploration of a less well defined pericyclic sequence.

**Suggested solution**

DDQ oxidizes the position between the two carbonyl groups to insert an alkene conjugated with both. We can now put in some stereochemistry as the three-membered ring must be cis fused to both six-membered rings. The diene undergoes electrocyclic ring opening to form a seven-membered ring. This is a six-electron and therefore disrotatory reaction and the two bonds to the old three-membered ring are therefore allowed to rotate inwards—the only rotation that can give the product.

![Chemical structure image]
**PROBLEM 12**

Explain the following observations. Heating this phenol brings it into rapid equilibrium with a bicyclic compound that does not spontaneously give the final product unless treated with acid.

![Chemical structure](image)

**Purpose of the problem**

A sigmatropic rearrangement involving a three-membered ring. The \(\sigma\)-bonds in three-membered rings are strained and more reactive than normal \(\sigma\)-bonds and take part readily in pericyclic reactions.

**Suggested solution**

The first step is a Cope rearrangement—a [3,3]-sigmatropic rearrangement made favourable in this case because the \(\sigma\)-bond that is broken is in a three-membered ring. The product cannot go directly to an aromatic compound as that would require a [1,3] (or a [1,7] depending on how you count) hydrogen shift. Such a shift would have to be antarafacial on the \(\pi\)-system and that is impossible in such a rigid structure.

![Chemical structure](image)

The aromatization can happen instead by an ionic mechanism. If the extended enol is protonated at the remote end, it can lose a proton from the ring junction to reform the phenol.

![Chemical structure](image)

---

This reaction was carried out as part of a mechanistic study by E. N. Marvell and S. W. Almond, *Tetrahedron Lett.*, 1979, 2777.
PROBLEM 13

Treatment of cyclohexa-1,3-dione with this acetylenic amine gives a stable enamine in good yield. Refluxing the enamine in nitrobenzene gives a pyridine after a remarkable series of reactions. Fill in the details, give mechanisms for the reaction, structures for the intermediates, and suitable explanations for each pericyclic step. A mechanism is not required for the last step as nitrobenzene simply acts as an oxidant.

Purpose of the problem

Practice in unravelling complicated reaction sequences involving pericyclic steps.

Suggested solution

The formation of the enamine requires only patient adding and subtracting of protons.

The cascade of reactions in hot nitrobenzene starts with a [3,3]-sigmatropic rearrangement that is unusual in that it forms an allene but is otherwise straightforward. To get to the next intermediate, we must go from the ketone to the enol and back again, but with the alkene now in conjugation.
Now we can transfer a proton from nitrogen to the middle of the allene. This is formally a [1,5]-H shift and is, of course, allowed, but it may be an ionic reaction as nitrogen is involved. This gives a diene that can twist round for a six-electron electrocyclic reaction. This is no doubt disrotatory but we can’t tell as no stereochemistry is involved.

PROBLEM 1
Rearrangements by numbers: just draw a mechanism for each reaction.

Purpose of the problem
This problem is just to help you acquire the skill of tracking down rearrangements by numbering (arbitrarily) the atoms in the starting material and working out where they’ve gone in the product.

Suggested solution
The first reaction is the preparation of Corey’s ‘OBO’ protecting group for carboxylic acids. The Lewis acid complexes one of the oxygen atoms and all the atoms of the starting material survive in the product. Atoms 3 and 5 are easy to identify in the product and it doesn’t much matter which of the CH₂ groups you label 1, 2, and 4. Of course you may use a completely different numbering system and that’s fine. The dotted lines show which new bonds are made and which old bonds are broken.
There is more than one reasonable mechanism: here are two possibilities, the second being perhaps the better.

The second reaction is even easier to work out. Atoms 2 and 3 are easy to find and they identify 1 and 4 in the product.

As the compounds are acetals we must use oxonium ions and not S_N2 reactions. Loss of BF_3 and rotation of the last intermediate gives the product.

The third reaction involves a cyclization. Atoms 1 and 7 clearly make the new bond and the rest of the atoms fit into place except that the bromine has gone and the alkene has moved from 7/8 to 8/9. Zinc inserts oxidatively into the C–Br bond and the mechanism follows from the nucleophilic nature of the organometallic compound.
PROBLEM 2

Explain this series of reactions.

Purpose of the problem

Working out the stereochemistry and mechanism of the Beckmann rearrangement.

Suggested solution

The first reaction forms the oxime by the usual mechanism (chapter 11). This reaction is under thermodynamic control so the OH group will bend away from the aryl substituent. Then we have the Beckmann rearrangement itself (p. 958 of the textbook). The group anti to the OH group migrates from C to N and that gives the product after rehydration and adjustment of protons.

PROBLEM 3
Draw mechanisms for the reactions and structures for the intermediates. Explain the stereochemistry, especially of the reactions involving boron. Why was 9-BBN chosen as the hydroborating agent?

Purpose of the problem
Rearrangements involving boron and a ring-closing rearrangement of sorts plus stereochemistry.

Suggested solution
The starting material is symmetrical so it doesn’t matter which face of which alkene you attack. The only important things are that boron binds to the more nucleophilic end of the alkene and that R₂B and H are added cis. Alkaline H₂O₂ makes the hydroperoxide anion (HOO⁻) which attacks boron.

The mesylate cyclizes in aqueous base. The more nucleophilic end of the remaining alkene displaces the mesylate with inversion to make the cis ring junction much preferred by the 5,5 fused system. Water adds to the tertiary cation to give the next intermediate.
Elimination of the alcohol (E1 of course as it is tertiary) gives the alkene and a repeat of the hydroboration from the outside (convex face) of the folded molecule gives the final alcohol with five new stereogenic centres.

9-BBN was chosen because it is very large and reinforces the natural electronic preference of boron to bind to the less substituted end of the alkene with an extra steric effect. It also has bridgehead atoms bound to boron and they make poor migrating groups, forcing the migration of the third B substituent.

**PROBLEM 4**

It is very difficult to prepare three-membered lactones. One attempted preparation, by the epoxidation of di-t-butyl ketone, gave an unstable compound with an IR stretch at 1900 cm⁻¹. This compound decomposed rapidly to a four-membered ring lactone that could be securely identified. Do you think they made the three-membered ring?

**Purpose of the problem**

Rearrangements as a proof of structure?
Suggested solution

The expected three-membered lactone would have a very high carbonyl stretching frequency because of ring strain. Three-membered cyclic ketones have carbonyl stretches at about 1815 cm⁻¹ and lactones have higher frequencies than ketones. So it might be the lactone. If it is, we should find a mechanism for the ring expansion to the four-membered lactone isolated. There is a good mechanism involving migration of a methyl group from one of the t-butyl groups. The general conclusion is that R. Wheeland and P. D. Bartlett did indeed make the first α-lactone.

PROBLEM 5
Suggest a mechanism for this rearrangement.

Purpose of the problem
Working out the mechanism of a new rearrangement.

Suggested solution
The starting material is an enamine and will react with bromine in the manner of an enol. Addition of hydroxide gives the starting material for the rearrangement. Notice that the nitrogen atom migrates rather than the carbon atom and this suggests that it does so by participation. If you numbered the atoms you would have found that the gem-dimethyl group and the nitrogen atom give the answer away immediately.
PROBLEM 6
A single enantiomer of the epoxide below rearranges with Lewis acid catalysis to give a single enantiomer of the product. Suggest a mechanism and comment on the stereochemistry.

Purpose of the problem
An unusual group migrates and stereochemistry gives a clue to mechanism.

Suggested solution
The mechanism for the reaction must involve Lewis acid complexation of the epoxide oxygen atom, cation formation, and migration of CO$_2$Et. This last point may surprise you but inspection of the product shows that CO$_2$Et is indeed bonded to the other carbon of what was the epoxide.

Although something like this must happen, our mechanism raises as many questions as it answers:

- Why does that bond of the epoxide open? *Answer.* Because the tertiary benzylic cation is much more stable than a secondary cation with a CO$_2$Et substituent.
- Why does CO$_2$Et migrate rather than the H atom? *Answer.* For the same reason! If the H atom migrates, the product would be a cation (or at least a partial positive charge would appear in the transition state) next to the CO$_2$Et group.
Surely the carbocation intermediate is planar and the product would be racemic? Answer. This was the purpose of the investigation. One chiral centre is lost in the reaction so only absolute stereochemistry is relevant. One explanation is that the cation is short-lived and that bond rotation is fast in the direction shown (the CO$_2$Et group is already down and has to rotate by only 30° to get to the right position for migration). The other is that migration is concerted with epoxide opening. This looks unlikely as the overlap is poor.

![Mechanism of carbocation formation](image)

**PROBLEM 7**

The ‘pinacol’ dimer of cyclobutanone rearranges with expansion of one of the rings in acid solution to give a cyclopentanone fused spiro to the remaining four-membered ring. Draw a mechanism for this reaction. Reduction of the ketone gives an alcohol that rearranges to a bicyclic alkene also in acid. Suggest a mechanism for this reaction and suggest why the rearrangements happen.

![Mechanism of pinacol rearrangement](image)

**Purpose of the problem**

An illustration of the easy rearrangement of four-membered rings to form five-membered rings.

**Suggested solution**

The first reaction is a simple pinacol rearrangement. The diol is symmetrical so protonation of either alcohol and migration of either C–C bond give the product.

![Mechanism of pinacol rearrangement](image)
Reduction to the alcohol is trivial and then acid treatment allows the loss of water and ring expansion of the remaining four-membered ring. You may well have drawn this as a stepwise process. Elimination gives the most substituted alkene. Both rearrangements occur very easily because of the relief of strain in going from a four- to a five-membered ring.

![Diagram of the reduction process]

**PROBLEM 8**

Give the products of Baeyer-Villiger rearrangements on these compounds, with reasons.

![Compounds for Problem 8]

**Purpose of the problem**

Prediction in rearrangements is as important as elsewhere and the Baeyer-Villiger is one of the more predictable rearrangements.

**Suggested solution**

There are a few minor traps here that we’re sure you’ve avoided. The first compound has two carbonyl groups but esters don’t do the Baeyer-Villiger rearrangement so only the ketone reacts. The more substituted carbon migrates with retention of configuration. The aldehyde rearranges with migration of the benzene ring in preference to the hydrogen atom. The last compound is $C_2$ symmetric so it doesn’t matter which group you migrate as long as you ensure retention of configuration. Take care when drawing the product as the migrating group has to be drawn the other way up.

![Compounds for Suggested solution]
PROBLEM 9
Suggest mechanisms for these rearrangements, explaining the stereochemistry in the second reaction.

Purpose of the problem
Unravelling one rearrangement after another with some stereochemistry.

Suggested solution
The first reaction is a simple ring expansion. The amine is not involved, presumably because it is fully protonated. The final loss of proton might be concerted with the migration as this would help explain the position of the alkene in the product.

The second reaction starts with bromination of the alkene and interception of the bromonium ion by the amine. Only when bromine adds to the opposite face of the alkene can the amine cyclize so this reaction resembles iodolactonization. Probably the bromination is reversible.
Finally, the weak base bicarbonate ($\text{HCO}_3^-$) is enough to remove a proton from the nitrogen atom and allow participation in nitrogen migration by displacement of bromide. This alkene is formed because the C–N' bond to tertiary carbon is broken preferentially.

**PROBLEM 10**

Give mechanisms for these reactions that explain any selectivity.

**Purpose of the problem**

To show that ring expansion from three- to four-membered rings and ring contraction the other way are about as easy.

**Suggested solution**

The first mechanism is a pinacol rearrangement and the compound is symmetrical so it doesn’t matter which alcohol is protonated. Both three- and four-membered rings are strained and the $\sigma$-bonds are more reactive than normal (they have a high energy HOMO). This makes ring contraction an easy reaction even though the strain is not relieved.

The second example looks at first to be a similar pinacol rearrangement. But the resulting ketone cannot easily be transformed into the product.
Breaking open one of the three-membered rings gets us off to a better start. This gives a hydroxy-ketone that can rearrange in a pinacol fashion with ring expansion of the remaining cyclopropane.

PROBLEM 11
Attempts to produce the acid chloride from this unusual amino acid by treatment with SOCl₂ gave instead a β-lactam. What has happened?

Purpose of the problem
To show that ring expansion in small rings is even easier in heterocycles because of participation.

Suggested solution
The formation of the acid chloride might go to completion or it might be that some intermediate on the way to the acid chloride rearranges. We shall use an intermediate. Whichever you use, it is participation by nitrogen that starts the ring expansion going, though the next intermediate is very unstable. When chloride attacks the bicyclic cation, it cleaves the most strained bond, the one common to two three-membered rings.
PROBLEM 12

Treatment of this hydroxy-ketone with base followed by acid gives the enone shown. What is the structure of intermediate A, how is it formed, and what is the mechanism of its conversion to the final product?

Purpose of the problem

Fragmentation may be followed by another reaction.

Suggested solution

Removal of the hydroxyl proton by the base promotes a fragmentation that is a reverse aldol reaction. It works because the C–C bond being broken is in a four-membered ring. Then an acid catalysed aldol reaction in the normal direction and elimination via the enol (E1cB) allows the formation of the much more stable six-membered ring.
PROBLEM 13
Just to check your skill at finding fragmentations by numbers, draw the mechanism for each of these one-step fragmentations in basic solution with acidic work-up.

Purpose of the problem
As the problem says, to help you unravel simple fragmentations.

Suggested solution
We can identify the six-membered ring in both compounds—the sequence 1–6 is clearly the same in both with a side chain at C3. The fragmentation is easy enough too—the OH proton is removed and the mesylate must be the leaving group so the groups doing the ‘pushing’ and ‘pulling’ are clear from the start.

The two CO₂H groups in the second product might cause a moment’s concern but one is on a –CH₂–CH₂– side chain and the other is at a branch point and we can soon fill in the rest of the numbers.
Clearly the OH proton is removed and one of the carboxyls is a leaving group. The stereochemistry disappears in the fragmentation but it is important, as the conformational drawing shows. One lone pair on the O⁻, the bond being fragmented, and the bond to the leaving group are all parallel (shown in thick lines).

**PROBLEM 14**

Explain why both these tricyclic ketones fragment to the same diastereoisomer of the same cyclo-octane.

**Purpose of the problem**

Fragmentations linked to ester hydrolysis.

**Suggested solution**

It is obvious from the reactions that two features have disappeared from the starting materials: an ester group (OAc) and a four-membered ring. The ester can be hydrolysed by KOH and the four-membered ring disappears in the fragmentation. As usual, draw the mechanism first and worry about the stereochemistry later. For the first compound, this sequence gives the enolate of a diketone and hence the diketone itself.
The second compound follows the same sequence and a different enolate emerges, but it is simply another enolate of the same ketone. Both compounds give the same basic structure.

But what about stereochemistry? We are not told the stereochemistry of the starting materials but know that 5,4 fused rings must have a cis ring junction. This junction survives in the first compound so the stereochemistry must have changed. The second compound gives us the clue as to how. When it tautomerizes to the ketone it will select the more stable trans 8,5 ring junction. In the same way, the enolate from the first sequence is in equilibrium under the reaction conditions with all the other enolates of the same ketone, including those at ring junctions. This is a stereotype selective reaction.
PROBLEM 15
Suggest a mechanism for this fragmentation and explain the stereochemistry of the alkenes in the product. This is a tricky problem, but find the mechanism and the stereochemistry will follow.

Purpose of the problem
Probably the most beautiful application of fragmentation yet by a true genius of chemistry, Albert Eschenmoser.

Suggested solution
The tosylate is obviously the leaving group, the two oxygens in the ring must become the ester group, and the CO$_2^-$ must leave as CO$_2$. All that remains is to trace a pathway from CO$_2^-$ to OTs via one of the ring oxygens using parallel bonds. Though you could draw a mechanism for this double fragmentation, it is not convincing. The only electrons anti-parallel to the C–OTs bond are those in the ring junction bond and the equatorial lone pair on one of the ring oxygens. Marking these with heavy lines, we carry out the first fragmentation. We’ve also drawn in the hydrogen that ends up on the alkene so you can see clearly where the trans geometry comes from.

The second fragmentation is easier to see if we redraw the intermediate so that we can see which groups are antiparallel. A conformational drawing also reveals the correct alkene geometry.
PROBLEM 16
Suggest a mechanism for this reaction and explain why the molecule is prepared to abandon a stable six-membered ring for a larger ring.

Purpose of the problem
A simple example of fragmentation used to create a medium size (11-membered) ring.

Suggested solution
The strong base removes the proton from the OH group and the oxyanion attacks one of the carbonyl groups (they are the same). This intermediate might decompose back to starting materials but it can also fragment with the loss of an enolate. The product is then an ester, and protonation of the enolate completes the reaction. The eleven-membered ring is more stable than usual because of the benzene ring (see problem 2, chapter 34), and because the ester does not suffer from cross-ring interactions in its favoured s-trans conformation.

J. R. Mahajan and H. de Carvalho, 
*Synthesis*, 1979, 518.
PROBLEM 17
Give mechanisms for these reactions, comment on the fragmentation.

Purpose of the problem
Revision of conjugate addition of enols, another ring expansion with an enolate as leaving group and an interesting piece of stereochemistry.

Suggested solution
The first step is enamine formation and the second is conjugate addition. This appears to lead to a dead end as we cannot find a way to make the intermediate from the product.

The answer is to exchange the enamine of the ketone with the enamine of the aldehyde. Under the conditions, enamine formation is reversible and
there are various ways you could draw details. Cyclization of this compound now gives the intermediate we are looking for.

The last two diagrams show where the stereochemistry comes from. The final product has a chair six-membered ring. The 1,3-bridge on the bottom of this ring must be diaxial or it cannot reach round. The pyrrolidine is equatorial and the five-membered ring must be cis fused. No doubt the stereochemistry as well as the intermediates are under thermodynamic control.

Finally the fragmentation itself. Methylation of the nitrogen makes it into a leaving group and addition of hydroxide to the ketone provides the electronic push. Notice that the C–N' bond, the C–C bond being fragmented, and a lone pair on the O' group are all parallel. The stereochemistry is already there in the intermediate.

**PROBLEM 18**
Suggest mechanisms for these reactions, explaining the alkene geometry in the first case. Do you consider that they are fragmentations?
**Purpose of the problem**

Simple fragmentations involving the opening of three-membered rings.

**Suggested solution**

The first reaction is a fragmentation without any ‘push’ but that is all right because the bond that is being broken is in a three-membered ring. You may have drawn a concerted mechanism or a stepwise one with a cation as intermediate. Either may be correct. The stereochemistry of the alkene is thermodynamically controlled.

![Diagram of first reaction with HBr and HBrO3 reactions](image1)

The second reaction is base-catalysed and starts with the hydrolysis of the ester by NaOH. This fragmentation also needs ‘push’, though only a three-membered ring is being broken, because the leaving group is an enolate, nowhere near as electron-withdrawing as the water molecule or the carbocation in the first example. Are they fragmentations? In both cases a C–C bond is being broken but we would understand if you felt the first was not strictly a fragmentation, particularly if it goes stepwise. Neither reaction breaks the molecule into three pieces and the terminology is merely a matter of opinion.

![Diagram of second reaction with NaOH and NaOAc reactions](image2)
PROBLEM 19
What steps would be necessary to carry out an Eschenmoser fragmentation on this ketone, and what products would be formed?

Purpose of the problem
Revision of an important and complex reaction involving fragmentation.

Suggested solution
The Eschenmoser fragmentation (p. 965 of the textbook) uses the tosylhydrazone of an α,β-epoxy-ketone. The epoxide can be made with alkaline hydrogen peroxide and the tosylhydrazone needs just tosylhydrazine to form what is essentially an imine. Then the fun can begin. The stereochemistry doesn’t matter for once.

The fragmentation is initiated with base that removes the proton from the NHTs group. This anion fragments the molecule one way and then the oxyanion fragments it the other way with nitrogen gas and Ts⁻ as leaving groups. The product is an acetylenic aldehyde or ketone.
PROBLEM 20
Revision content. Suggest mechanisms for these reactions to explain the stereochemistry.

Purpose of the problem
Rearrangements and a fragmentation.

Suggested solution
The ring opening and the rearrangement cannot be concerted because the group on the ‘wrong’ side of the molecule migrates. There must be a cationic intermediate. In contrast, attack of bromide occurs stereospecifically from the side opposite the migrating group, so this is presumably concerted with the rearrangement.

The second reaction is a fragmentation. Silver(I) is an excellent Lewis acid for halogens and probably produces a secondary carbocation intermediate. Push from the OH group completes the fragmentation.

As it happens the starting epoxide is that of natural α-pinene so it and the product are single enantiomers. P. H. Boyle et al., J. Chem. Soc., Chem. Commun., 1971, 395.
Suggested solutions for Chapter 37

PROBLEM 1
Give a mechanism for the formation of this silylated ene-diol and explain why the Me₃SiCl is necessary.

Purpose of the problem
Reminder of an important radical reaction.

Suggested solution
This is an acyloin condensation linking radicals derived from esters by electron donation from a dissolving metal (here sodium). If the esters can form enolates, the addition of Me₃SiCl protects against that problem by removing the MeO⁻ by-product.

The first product is a very electrophilic 1,2-dione and it accepts electrons from sodium atoms even more readily than do the original esters. The product is an ene diolate that is also silylated under the reaction conditions.

PROBLEM 2
Heating the diazonium salt below in the presence of methyl acrylate gives a reasonable yield of a chloroacid. Why is this unlikely to be nucleophilic aromatic substitution by the $S_{N}1$ mechanism (p. 520 of the textbook)? Suggest an alternative mechanism that explains the regioselectivity.

\[
\begin{align*}
\text{Cl} & \quad \text{N}_2 \quad \text{Cl} \\
\text{Cl} & \quad \text{CO}_2\text{Me} \quad \text{heat} \\
\text{Cl} & \quad \text{CO}_2\text{Me} \\
\end{align*}
\]

**Purpose of the problem**
Revision of nucleophilic aromatic substitution with diazonium salts and contrasting cations and radicals.

**Suggested solution**
The cation mechanism is perfectly reasonable as far as the diazonium salt is concerned but it will not do for the alkene. Conjugated esters are electrophilic and not nucleophilic alkenes. Even if it were to attack the aryl cation, we should find the reverse regioselectivity.

\[
\begin{align*}
\text{Cl} & \quad \text{N}_2 \quad \text{Cl} \\
\text{Cl} & \quad \text{CO}_2\text{Me} \\
\text{Cl} & \quad \text{CO}_2\text{Me} \\
\text{Cl} & \quad \text{Cl} \\
\end{align*}
\]

The only way to produce the observed product is to decompose the diazonium salt homolytically. To do this we can draw the salt as a covalent compound or transfer one electron from the chloride ion to the diazonium salt. The other product would be a chlorine radical. Addition to the alkene gives the more stable radical which abstracts chlorine from the diazonium salt and keeps the chain going.
**PROBLEM 3**
Suggest a mechanism for this reaction and comment on the ring size formed. What is the minor product likely to be?

---

**Purpose of the problem**
Activated alkenes are not necessary in radical cyclizations.

**Suggested solution**
The peroxide is a source of benzoyl radicals (PhCO₂⁻) and these capture hydrogen atoms to give the most stable radical. The best one here is stabilized by both CN and CO₂Et. Cyclization onto the alkene gives mainly a secondary radical on a six-membered ring and this abstracts a hydrogen from starting material to complete the cycle.

The alternative is to add to the more substituted end of the alkene. This gives a less stable primary radical, but this ‘5-exo’ ring closure is often
preferred because the orbital alignment is better. The minor product has a five-membered ring.

PROBLEM 4
Treatment of this aromatic heterocycle with NBS (N-bromosuccinimide) and AIBN gives mainly one product but this is difficult to purify from minor impurities containing one or three bromine atoms. Further treatment with 10% aqueous NaOH gives one easily separable product in modest yield (50%). What are the mechanisms for the reactions?

Purpose of the problem
An important radical reaction: bromination at benzylic and allylic positions by NBS, and an application.

Suggested solution
Two preliminary reactions need to take place: NBS is a source of a low concentration of bromine molecules and AIBN initiates the radical chain by forming a nitrile-stabilized tertiary radical.

The new radical abstracts hydrogen atoms from the benzylic positions to make stable delocalized radicals. These react with bromine to give the benzylic bromide and release a bromine atom.
All subsequent hydrogen abstractions are carried out by bromine atoms, either of the kind we have just seen or to remove a hydrogen atom from the other methyl group. This reaction provides the HBr that generates more bromine from NBS.

Finally the dibromide reacts with NaOH to give the new heterocycle. Both $S_N2$ displacements are very easy at a benzylic centre and the second is intramolecular.

**PROBLEM 5**

Propose a mechanism for this reaction accounting for the selectivity. Include a conformational drawing of the product.

**Purpose of the problem**

Another important radical reaction: cyclization of alkyl bromides onto alkenes.
**Suggested solution**

This time AIBN abstracts the hydrogen from Bu₃SnH and the tin radicals carry the chain along. First they remove the bromine atom from the starting material to make a vinyl radical that cyclizes onto the unsaturated ketone to give a radical stabilized by conjugation with the carbonyl group. The chain is completed by abstraction of hydrogen from another molecule of Bu₃SnH, the tin radical formed then allowing the cycle to restart.

![Chemical diagram](image)

The stereochemistry of the product comes from the requirement of a 1,3-bridge to be diaxial as this is the only way the bridge can reach across the ring. At the moment of cyclization, the vinyl radical side chain must be in an axial position.

![Chemical diagram](image)
**PROBLEM 6**
An ICI process for the manufacture of the diene used to make pyrethroid insecticides involved heating these compounds to 500 °C in a flow system. Propose a radical chain mechanism for the reaction.

\[
\begin{align*}
\text{Cl} & \quad 500 \degree C \\
\text{Cl} & \quad \text{H} \\
\end{align*}
\]

**Purpose of the problem**
Learning how to avoid a trap in writing radical reactions and to show you that radical reactions can be useful.

**Suggested solution**
The most likely initiation at 500 °C is the homolytic cleavage of the C–Cl bond to release allyl and chloride radicals. The chloride radicals then attack the alkene and abstract a hydrogen atom to give more of the same allylic radical.

\[
\begin{align*}
\text{Cl} & \quad 500 \degree C \\
\text{Cl} & \quad \text{H} \\
\end{align*}
\]

The trap is to form the product by dimerizing the allylic radical. Dimerizing radicals does sometimes occur (in the acyloin reaction for example) but it is a rare process.

\[
\begin{align*}
\text{only rarely} \\
\end{align*}
\]

Much more likely is a chain reaction. If we add the allylic radical to the alkene part of the allylic chloride we make a stable tertiary radical that can lose chloride radical and propagate the chain.

\[
\begin{align*}
\text{Cl} & \quad \text{Cl} \\
\end{align*}
\]

The original workers at ICI suggested a different mechanism: D. Holland and D. J. Milner, *Chem. and Ind.* (London), 1979, 707.
PROBLEM 7
Heating this compound to 560 °C gives two products with the spectroscopic data shown below. What are they and how are they formed?

\[ \text{Cl} \quad 560 ^\circ C \quad \text{A} \quad \text{+} \quad \text{B} \]

**A** has IR 1640 cm \(^{-1}\); \( m/z \) 138 (100%) and 140 (33%), \( \delta_H \) (ppm) 7.1 (4H, s), 6.5 (1H, dd, \( J \) 17, 11 Hz), 5.5 (1H, dd, \( J \) 17, 2 Hz), and 5.1 (1H, dd, \( J \) 11, 2 Hz).

**B** has IR 1700 cm \(^{-1}\); \( m/z \) 111 (45%), 113 (15%), 139 (60%), 140 (100%), 141 (20%), and 142 (33%), \( \delta_H \) (ppm) 9.9 (1H, s), 7.75 (2H, d, \( J \) 9 Hz), and 7.43 (2H, d, \( J \) 9 Hz).

**Purpose of the problem**
Revision of structure determination and a radical reaction with a difference.

**Suggested solution**

Compound **A** contains chlorine \((m/z \) 138/140, 3:1) and that fits \( \text{C}_8\text{H}_7\text{Cl} \). It still has the 1,4-disubstituted benzene ring (four aromatic Hs) and it is an alkene (IR 1640) with three hydrogens on it with characteristic coupling. We can write the structure immediately as there is no choice. The four aromatic hydrogens evidently have the same chemical shift.

\[ \text{Cl} \quad \text{O} \quad \text{Cl} \quad 560 ^\circ C \quad \text{Cl} \quad \text{H} \quad \text{Cl} \]

\( \delta_H \) 6.5, 5.1, 5.5

Compound **B** has \( m/z \) 140/142, 3:1 and a carbonyl group (at 1700 cm \(^{-1}\)) which fits \( \text{C}_7\text{H}_5\text{ClO} \) and looks like an aldehyde \( (\delta_H \) 9.9). It still has the disubstituted benzene. The structure is even easier this time!

\[ \text{Cl} \quad \text{O} \quad \text{Cl} \quad 560 ^\circ C \quad \text{Cl} \quad \text{H} \quad \text{Cl} \]

\( \delta_H \) 7.75, 7.43, 9.9

So how are these products formed? At such high temperatures, \( \sigma \)-bonds break and the weakest bonds in the molecule are the C–C and C–O bonds in
the four-membered ring next to the benzene ring. Breaking these bonds releases strain and allows one of the radical products to be secondary and delocalized.

PROBLEM 8
Treatment of methylcyclopropane with peroxides at very low temperature (−150 °C) gives an unstable species whose ESR spectrum consists of a triplet with coupling of 20.7 gauss and fine splitting showing dtt coupling of 2.0, 2.6, and 3.0 gauss. Warming to a mere −90 °C gives a new species whose ESR spectrum consists of a triplet of triplets with coupling 22.2 and 28.5 gauss and fine splitting showing small ddd coupling of less than 1 gauss.

If methylcyclopropane is treated with t-BuOCl, various products are obtained but the two major products are C and D. At lower temperatures more of C is formed and at higher temperatures more of D.

Treatment of the more substituted cyclopropane below with PhSH and AIBN gives a single product in quantitative yield. Account for all these reactions, identifying A and B and explaining the differences between the various experiments.

Purpose of the problem
Working out the consequences of an important substituent effect on radical reactions: the cyclopropyl group.
Suggested solution

The peroxide is a source of \( t\text{-BuO}^- \) radicals and these abstract a hydrogen from the methyl group of the hydrocarbon. The first spectrum is that of the cyclopropylmethyl radical. The odd electron is in a \( p \) orbital represented by a circle and the planar \( \text{CH}_2^- \) group is orthogonal to the plane of the ring but the two \( H \)'s are the same because of rapid rotation. The odd electron has a large coupling to the two hydrogens (\( H^a \)) on the same carbon, a smaller doublet coupling to \( H^b \), and small couplings to the two \( H \)'s and two \( H^b \)'s. The coupling to \( H^b \) is small because the \( p \) orbital containing the odd electron is orthogonal to the \( C-H^b \) bond.

![Diagram of cyclopropylmethyl radical](image1)

Warming to \(-90^\circ C\) causes decomposition to an open-chain radical. The odd electron is coupled to the two hydrogens on its own carbon (\( H^a \)) and those on the next carbon (\( H^b \)) each giving a triplet (22.2 and 28.5). Coupling to the more remote hydrogens is small.

![Diagram of open-chain radical](image2)

Decomposition of the same hydrocarbon with \( t\text{-BuOCl} \) produces the same sequence of radicals but they can now be intercepted by the chlorine atom of the reagent, releasing more \( t\text{-BuO}^- \) radicals and a radical chain is started. At lower temperatures the ring opening is slower so more of the cyclopropane is captured.

![Diagram of radical chain](image3)

The last example also produces a radical next to a cyclopropane ring but this time it can decompose very easily to give a stable secondary benzylic radical. This captures a hydrogen atom from \( \text{PhSH} \) releasing \( \text{PhS}^- \) and maintaining an efficient radical chain. Ring opening of cyclopropanes is now a standard way of detecting radicals.
**PROBLEM 9**
The last few stages of Corey’s epibatidine synthesis are shown here. Give mechanisms for the first two reactions and suggest a reagent for the last step.

**Purpose of the problem**
Application of radical reactions in an important sequence plus revision of conformation and stereochemistry.

**Suggested solution**
The first step involves deprotonation of the rather acidic amide (the CF<sub>3</sub> group helps) and the displacement of the only possible bromide—the one on the opposite face of the six-membered ring as the SN<sub>2</sub> reaction must take place with inversion.

The second step is a standard dehalogenation by Bu<sub>3</sub>SnH. AIBN generates Bu<sub>3</sub>Sn· by hydrogen abstraction from the reagent and this removes the bromine. Make sure you complete the chain and do not use H· at any point.
Finally we need to hydrolyse the amide. This normally requires strong acid or alkali but the CF₃ group makes this amide significantly more electrophilic than most and milder conditions can be used. Corey actually used NaOMe in methanol at 13 °C for two hours and got a yield of 96%. Any reasonable conditions you may have chosen would be fine too.

**PROBLEM 10**

How would you make the starting material for this sequence of reactions? Give a mechanism for the first reaction that explains its regio- and stereoselectivity. Your answer should include a conformational drawing of the product. What is the mechanism of the last step? Attempts to carry out this last step by iodine/lithium exchange and reaction with allyl bromide failed. Why? Why is the alternative shown here successful?

**Purpose of the problem**

Application of radical reactions when the alternative ionic reactions fail.

**Suggested solution**

The starting material is an obvious Diels-Alder product as it is a cyclohexene with a carbonyl group outside the ring on the opposite side. The first step is iodolactonization. Iodine attacks the alkene reversibly on both sides but, when it attacks opposite the carboxylate anion, the lactone ring snaps shut.
The problem asks for a conformational drawing of the product and indeed that is necessary. The 1,3-lactone bridge must be diaxial as that is the only way for the carboxylate to reach across and therefore it must attack from an axial direction too.

\[
\begin{align*}
\text{initiation} & \quad \text{thereafter} \\
\text{NC} & \quad \text{Bu}_3\text{Sn}^- \\
\end{align*}
\]

The last step is initiated by AIBN which removes the iodine atom from the compound to make a secondary radical. This attacks the allyl stannane and the intermediate loses Bu$_3$Sn$^-$ and that takes over the job of removing iodine atoms to keep the chain going. The radical intermediate has no stereochemistry at the planar radical carbon and attack occurs from the bottom face to avoid the blocking lactone bridge.

Anionic reactions cannot be used for this allylation. If the iodine were metallated, the organometallic compound would immediately expel the lactone bridge as carboxylate ion is a good leaving group. The radical is stable because the C–O bond is strong and not easily cleaved in radical reactions.
PROBLEM 11

Suggest a mechanism for this reaction explaining why a mixture of diastereoisomers of the starting material gives a single diastereoisomer of the product. Is there any other form of selectivity?

\[
\text{OEt} \quad \text{O} \quad \text{Br} \\
\text{1. Bu}_3\text{SnH, AIBN} \\
\text{2. Cr(VI), H}_2\text{SO}_4 \\
\text{O} \quad \text{O} \\
\text{SnBu}_3 \quad \text{CN} \\
\text{initiation} \\
\text{thereafter}
\]

Purpose of the problem

A radical ring-closing reaction with a curious stereochemical outcome.

Suggested solution

The abstraction of bromine, at first by AIBN and thereafter by Bu₃Sn⁺ produces a radical that again does not eliminate but adds to an alkene. A five-membered ring is formed (this is usually the more favourable closure) by attack on the alkene on the opposite side from that occupied by the i-Pr group. The product is a mixture of diastereoisomers as no change occurs at the acetal centre.

Acid-catalysed oxidation first hydrolys the acetal and then oxidizes either the hemiacetal or the aldehyde to the lactone. Now the molecule is one diastereoisomer as the ambiguous centre is planar. The other form of selectivity is the ring size (see the textbook, p. 1000).
PROBLEM 12

Reaction of this carboxylic acid (C₆H₈O₂) with bromine in the presence of dibenzoyl peroxide gives an unstable compound A (C₅H₆Br₂O₂) that gives a stable compound B (C₅H₅BrO₂) on treatment with base. Compound B has IR 1735 and 1645 cm⁻¹ and NMR δH 6.18 (1H, s), 5.00 (2H, s) and 4.18 (2H, s). What is the structure of the stable product B? Deduce the structure of the unstable compound A and mechanisms for the reactions.

Purpose of the problem

Revision of structural analysis in combination with an important radical functionalization.

Suggested solution

The starting material is C₆H₈O₂ so the stable compound B has gained a bromine and lost three hydrogens. There must be an extra double bond equivalent (DBE) somewhere in B. The IR spectrum shows that the OH has gone and suggests a carbonyl group, possibly an ester because of the high frequency, and an alkene. The NMR shows that both methyl groups have gone and have been replaced by CH₂ groups. The bromine must be on one of them and the ester oxygen on the other. The extra DBE is a ring.

Since both methyl groups are functionalized, unstable A must have one Br on each methyl group. The peroxide produces benzoyl radicals that abstract protons from both allylic positions to give stabilized radicals that stack bromine molecules to give bromide radicals to continue the chain reaction. In base the carboxylate cyclizes onto the cis CH₃Br group.
Initially, the reaction proceeds with the formation of compound A, which is an unstable compound.

Thereafter, the reaction continues with the formation of compound B, which is a stable compound.

Base catalysis is involved in the conversion of unstable compound A to stable compound B.
Suggested solutions for Chapter 38

PROBLEM 1
Suggest mechanisms for these reactions.

Purpose of the problem
Two simple carbene reactions initiated by base.

Suggested solution
Going to the right we must remove the rather acidic proton from CHBr₃ to give the carbanion. This loses bromide to give dibromocarbene and insertion into cyclohexene gives the product.

The second reaction is very similar. α-Elimination of HCl gives a carbene that inserts into an alkene. These are the simplest reactions of carbenes and are very common.
PROBLEM 2
Suggest a mechanism for this reaction and explain the stereochemistry.

\[
\begin{align*}
\text{N}_2 & \quad \text{CuSO}_4 \\
\text{CO}_2\text{Me} & \quad \text{O} \\
\text{N}_2 & \quad \text{CuSO}_4 \\
\text{CO}_2\text{Me} & \quad \text{O}
\end{align*}
\]

Purpose of the problem
Another important carbene method used in the synthesis of a natural antibiotic.

Suggested solution
The diazo compound decomposes to gaseous nitrogen and a carbene under catalysis by Cu(II). Insertion into the exposed alkene gives the three-membered ring. The stereochemistry partly comes from the 'tether'—the linkage between the carbene and the rest of the molecule that delivers the carbene to the bottom face of the alkene. The rest comes from the inevitable cis fusion between the five- and three-membered rings.

PROBLEM 3
Comment on the selectivity shown in these reactions.

Purpose of the problem
A study in chemoselectivity during carbene insertion into alkenes.
Suggested solution

The first reaction is a variation on Simmons-Smith cyclopropanation. Though strictly a carbenoid rather than a carbene, it delivers a CH₂ group from an organozinc compound bound to an oxygen atom, in this case the OMe group. Only that alkene reacts.

The second cyclopropanation occurs at the only remaining alkene with a carbene generated from a diazoester. The stereoselectivity comes from attack on the opposite side of the ring from the already established cyclopropane.

PROBLEM 4
Suggest a mechanism for this ring contraction.

Purpose of the problem

Drawing mechanisms for a rearrangement involving a carbene formed photochemically.

There is little selectivity for the stereochemistry of the CO₂Et group but this fortunately did not matter in the synthesis of a natural defence substance from a sponge by G. A. Schieser and J. D. White, J. Org. Chem., 1980, 45, 1864.
**Suggested solution**

The carbene formed by loss of nitrogen from the diazoketone rearranges with the migration of either C–C bond to give a ketene picked up by methanol.

**PROBLEM 5**

Suggest a mechanism for the formation of this cyclopropane.

**Purpose of the problem**

An unusual type of carbene but it behaves normally.

**Suggested solution**

There is no doubt that t-BuO⁻ is a base, but which proton does it remove? The OH proton perhaps, but that doesn't lead to a carbene. The proton on the alkyne? That molecule has a leaving group, but is it too far away?

Not if you push the electrons through the molecule in a γ-elimination. Normal elimination is β-elimination: both α- and γ-elimination can produce carbenes. The arrows are easy to make sense of if you think of a carbene as a carbon with both a + and a − charge. The carbene is an allenyl carbene with no substituent at the carbene centre. It inserts into the alkene in the other molecule.
**Problem 6**

Decomposition of this diazo compound in methanol gives an alkene \( \text{A} \) (\( \text{C}_8\text{H}_{14}\text{O} \)) whose NMR spectrum contains two signals in the alkene region: \( \delta \) 3.50 (3H, s), 5.50 (1H, dd, \( J \) 17.9, 7.9), 5.80 (1H, ddd, \( J \) 17.9, 9.2, and 4.3), 4.20 (1H, m) and 1.3–2.7 (8H, m). What is its structure and geometry?

When you have done that, suggest a mechanism for the reaction using this extra information: Compound \( \text{A} \) is unstable and even at 20 °C isomerizes to \( \text{B} \). If the diazo compound is decomposed in methanol containing a diene, compound \( \text{A} \) is trapped as the adduct shown. Account for all these reactions.

**Purpose of the problem**

Revision of structural analysis, alkene geometry, and cycloadditions with carbenes as a mechanistic link.

**Suggested solution**

The starting material is \( \text{C}_7\text{H}_{10}\text{N}_2 \) so it has lost nitrogen and gained \( \text{CH}_3\text{O} \)—one molecule of methanol. We can see the MeO group at \( \delta \) 3.50 and the four CH\(_2\) groups in the ring are still there (8H m at 1.3–2.7). All that is left is a multiplet at \( \delta \) 4.2, obviously next to OMe, and a pair of alkene protons at \( \delta \) 5.5 and 5.8, coupled with \( J \) 17.9—obviously a \textit{trans} alkene. That at \( \delta \) 5.5 is coupled to one proton and the one at 5.8 is coupled to two. We now have these fragments:
But these add up to $C_5H_5$ too much! Clearly the CH attached to OMe and the CH attached to the alkene are the same atom and the CH$_3$ at the other end of the alkene must be one end of the chain of four CH$_3$s. We now have a structure but it doesn’t join up!

This is the test of your belief in spectroscopy—the dotted ends must join up to give A. Yes, this does put an $E$-alkene in a seven-membered ring, and it is difficult to draw, but you were warned that A is unstable. The CH$_2$ group next to the CHOMe group is diastereotopic so the coupling constants are different.

Now that we know the structure of A, it is easy enough to find a mechanism. Loss of nitrogen produces a carbene that gives an allene in a pericyclic process and this twisted compound (the two alkenes are at 90° to each other) and protonation gives the $trans$ alkene as a cation that reacts with methanol to give A.

The twisted alkene is unstable and rotates to the much more stable $cis$ alkene even at 20 °C. It can rotate because the overlap between the p orbitals is weak as they are not parallel. Trapping in a Diels-Alder reaction preserves the $trans$ stereochemistry.

---

This was the discovery of H. Jendralla, *Angew. Chem. Int. Ed. Engl.*, 1980, 19, 1032. If you were really on the ball, you’ll have noticed that a $trans$-cycloheptene is chiral, so this compound must be a single diastereoisomer though we don’t know which.
**Problem 7**

Give a mechanism for the formation of the three-membered ring in the first of these reactions and suggest how the ester might be converted into the amine with retention of configuration.

\[
\text{Ph} = \text{N}_2 = \text{CO}_2\text{Et} \xrightarrow{\text{Cu}(I)} \text{Ph} \text{CH} = \text{CO}_2\text{Et} \xrightarrow{?} \text{Ph} \text{NH}_2
\]

**Purpose of the problem**

A routine carbene insertion and a reminder of nitrenes as analogues of carbenes.

**Suggested solution**

The diazoester gives the carbene under Cu(I) catalysis and insertion into the alkene follows its usual course. The only extra is stereoselectivity: the insertion happens more easily if the two large groups (Ph and CO\text{$_2$}Et) keep as far apart as possible.

\[
\text{N}_2 = \text{CO}_2\text{Et} \xrightarrow{\text{Cu}(I)} \text{Ph} \text{CH} = \text{CO}_2\text{Et} \rightarrow \text{Ph} \text{CH} = \text{CO}_2\text{Et}
\]

Conversion of acid derivatives into amines with the loss of the carbonyl group can be done in various ways. In chapter 36 we recommended the Curtius and the Hofmann. The Hofmann degradation is the easier if we start with an ester, converting into the amide with ammonia and then treating with bromine in basic solution. The N-bromo amide undergoes $\alpha$-elimination to a nitrene that rearranges to an isocyanate.

\[
\text{Ph} \text{CO}_2\text{Et} \xrightarrow{\text{NH}_3} \text{Ph} \text{CONH}_2 \xrightarrow{\text{Br}_2, \text{NaOH}} \text{Ph} \text{N} = \text{C}=\text{O}
\]

PROBLEM 8
Explain how this highly strained ketone is formed, albeit in very low yield, by these reactions. How would you attempt to make the starting material?

Purpose of the problem
To show that intramolecular carbene insertion is a powerful way to make cage compounds.

Suggested solution
Oxalyl chloride makes the acid chloride, and diazomethane converts this into the diazoketone.

Now the carbene chemistry. Treatment with Cu(I) removes nitrogen and forms the carbene. Remarkably, this is able to reach across the molecule and insert into the alkene, thus forming one three- and two new four-membered rings in one step. You will not be surprised at the yield: 10%.

How would you attempt to make the starting material? The original workers used another carbene reaction—the Cu(I) catalysed insertion of a diazoester into bis-trimethylsilyl acetylene.
PROBLEM 9
Attempts to prepare compound A by phase-transfer catalysed cyclization required a solvent immiscible with water. When chloroform (CHCl₃) was used, compound B was formed instead and it was necessary to use the more toxic CCl₄ for success. What went wrong?

Purpose of the problem
Carbene chemistry is not always what is wanted: how do you avoid it?

Suggested solution
Product B is clearly the adduct of product A and dichlorocarbene which must have come from the chloroform and base. The good news is that product A was evidently formed in the basic reaction mixture so, if we simply avoid a solvent that is also a carbene source, all is well.

PROBLEM 10
Revision content. How would you carry out the first step in this sequence? Propose mechanisms for the remaining steps explaining any selectivity.

Purpose of the problem
Revision of specific enol formation, rearrangement reactions, electrocyclic reactions and conjugate addition plus some carbene chemistry.

Suggested solution
The first step requires a specific enol from an enone. Treatment with LDA achieves kinetic enolate formation by removing one of the more acidic hydrogens immediately next to the carbonyl group. The lithium enolate is trapped with Me₃SiCl to give the silyl enol ether.

The next step is dichlorocarbene insertion into the more nucleophilic of the two alkenes. Dichlorocarbene is an electrophilic carbene so the main interaction is between the HOMO ($\pi$) of the alkene and the empty p orbital of the carbene. The carbene is formed by decarboxylation, a process that needs no strong base.
You can draw the ring expansion in a number of ways. All start with the removal of the Me₃Si group with water. You might then simply use a one-step mechanism (a) but an electrocyclic process via the cyclopropyl cation (b) might be better. This is allowed since the inevitable cis ring junction requires H and OH to rotate outwards.

Finally, a double conjugate addition of MeNH₂ to the dienone forms the bicyclic amine. Conjugate addition probably occurs first on the more electrophilic chloroenone, though it doesn’t much matter. There is some stereoselectivity in that the remaining chlorine prefers the equatorial position on the new six-membered ring but this is thermodynamic control as that position is easily enolized.

PROBLEM 11
How would you attempt to make these alkenes by metathesis?
**Purpose of the problem**

Applications of this important and powerful method.

**Suggested solution**

Metathesis is usually *E*-selective and these are both *E*-alkenes so prospects are good. We must disconnect each compound at the alkene and add something to the end of each, probably just CH₂ as the by-product will then be volatile ethylene.

Each starting material must now be made. The stereochemistry of the first tells us that we should add an allyl metal compound to an epoxide. The metathesis catalyst will be one of those mentioned in the chapter.

The second molecule is not symmetrical but this is all right as it will be an intramolecular (ring-closing) metathesis so we can expect few cross-products. There are many ways to make the starting material: alkylation of a ketone is probably the simplest though conjugate addition would have its advantages. The same catalyst can be used and very little would be needed.
PROBLEM 12
Heating this acyl azide in dry toluene under reflux for three hours gives a 90% yield of a heterocycle. Suggest a mechanism, emphasizing the role of any reactive intermediates.

![Chemical structure diagram](image)

**Purpose of the problem**
Demonstrating the practical nature of nitrene chemistry in the context of heterocyclic synthesis.

**Suggested solution**
Heating an azide liberates nitrogen gas and forms a nitrene. In this case, rearrangement to an isocyanate is followed by intramolecular nucleophilic attack by the ortho amino group.

![Mechanism diagram](image)

PROBLEM 13
Give mechanisms for the steps in this conversion of a five- into a six-membered aromatic heterocycle.

![Chemical structure diagram](image)

**Purpose of the problem**
It is the turn of carbene chemistry to show its usefulness in that most practical of all subjects: heterocyclic synthesis.
Suggested solution

Decomposition of trichloroacetate ion releases the Cl₃C⁻ carbanion. Loss of chloride gives dichlorocarbene and addition to one of the double bonds in the pyrrole gives a bicyclic intermediate.

Ring expansion can be drawn in various ways. There is a direct route from the neutral amine, or its anion, that doesn’t look very convincing, or you can ionize one of the chlorides first and open the cyclopropyl cation in an electrocyclic reaction. However you explain it, this is a good way to make 3-substituted pyridines.
Suggested solutions for Chapter 39

PROBLEM 1
Propose three fundamentally different mechanisms (other than variations of the same mechanism with different kinds of catalysis) for this reaction. How would (a) D labelling and (b) ¹⁸O labelling help to distinguish the mechanisms? What other experiments would you carry out to rule out some of these mechanisms?

Purpose of the problem
Investigating a reaction where there are several reasonable mechanisms.

Suggested solution
The reaction is an ester hydrolysis so the obvious mechanism is to attack the carbonyl group with hydroxide. Notice that we draw out each stage of the mechanism and do not use any summary or shorthand.

Mechanism 1: Normal ester hydrolysis
But the ester oxygen atom is attached to an aromatic ring with a para nitro group. Nucleophilic aromatic substitution would give the same product.

Mechanism 2: Nucleophilic aromatic substitution
Finally, the ester can be transformed into an enolate, using hydroxide as a base. Elimination gives a ketene that can be attacked by hydroxide as a nucleophile to give the product.

**Mechanism 3: Enolate elimination to give a ketene**

Mechanism 3 requires the exchange of at least one hydrogen atom with the solvent so, if D$_2$O were used as the solvent, or better deuterated starting material were used, the exchange of one whole deuterium atom would indicate mechanism 3 while no exchange, or only minor amounts from the inevitable enolization, would show mechanisms 1 or 2. In mechanisms 1 and 3, the added OH group ends up in CO$_2$H but in mechanism 2 it ends up as the phenol. Using H$_2$¹⁸O as solvent, or better labelling the ester oxygen as $^{18}$O would separate mechanisms 1 and 3 from 2.

Other experiments we could do might include trying to trap the ketene intermediate in a [2 + 2] cycloaddition, studying the reaction by UV, hoping to see the release of $p$-nitrophenolate in mechanism 3, changing the structure of the starting material so that one or other of the mechanisms would be difficult, even measuring the effects of the substituent on the benzene ring on the rate, or looking for a deuterium isotope effect in the labelled lactone.
PROBLEM 2

Explain the stereochemistry and labelling pattern in this reaction.

Purpose of the problem

A combination of labelling and stereochemistry reveals the details of a surprisingly interesting rearrangement.

Suggested solution

The randomization of the label and the racemization suggest that the carboxylate falls off the allyl cation and then comes back on again at either end. While they are detached the distinction between the two ends of both cation and anion disappears as they are delocalized.

The product is racemic because the two intermediates each have a plane of symmetry and are achiral. The retention of relative stereochemistry (formation of the trans product from trans starting material) could result from stereoselective recombination (the two faces of the allyl cation are not the same) or from the two ions sticking together as an ion pair so that the acetate slides across one face of the cation. An alternative [3,3] sigmatropic rearrangement would not randomize the labels in the same way.

This question is based on more complex chemistry described by H. L. Goering et al., J. Am. Chem. Soc., 1964, 86, 1951.
PROBLEM 3
The Hammett ρ value for migrating aryl groups in the acid-catalysed Beckmann rearrangement is –2.0. What does that tell us about the rate-determining step?

Purpose of the problem
The Hammett relationship gives an intimate picture of the Beckmann rearrangement.

Suggested solution
The normal mechanism for the Beckmann rearrangement (pp. 958–960 of the textbook) involves protonation at OH and migration of the group anti to the N–O bond: in this case the substituted benzene ring.

![Chemical reaction diagram]

If this mechanism is correct here, we should expect the migration itself to be the slow step. The first step is just a proton transfer to oxygen and must be fast. The steps after the migration involve attack of water on a carbocation and proton transfers to O and N and these must all be fast. The migration breaks a C–C bond, forms a C–N bond and creates an unstable cation. But does this agree with the evidence? Starting material and product in the migration step are cations so the transition state must be a cation too. Any contribution to cation stability made by the migrating group should help and we should therefore expect electron-donating groups to migrate faster. This is what we see: a ρ value of –2.0 shows a modest acceleration by electron-donating groups (p. 1041 ff.).

In the Beckmann rearrangement, the anti group migrates but in other rearrangements the migrating group is chosen for a very different reason: it is normally the group that is best able to stabilize a positive charge and benzene rings can do this by π participation. This would be the participation mechanism:
The Hammett $\rho$ value of $-2.0$ gives very definite evidence that participation does not occur. If it did the closure of the unstable three-membered ring would be the slow step and a positive charge would form on the benzene ring itself. This would give a much larger $\rho$ value of something like $-5.0$. One reason that participation does not occur is that the starting material is planar and the $p$ orbitals in the benzene ring cannot point in the right direction to interact with the $\sigma^*$ orbital of the N–O bond. They are orthogonal to it.

**PROBLEM 4**

Between pH 2 and 7 the rate of hydrolysis of this ester is independent of pH. At pH 5 the rate is proportional to the concentration of acetate ion ($\text{AcO}^-$) in the buffer solution and the reaction goes twice as fast in $\text{H}_2\text{O}$ as in $\text{D}_2\text{O}$. Suggest a mechanism for the pH-independent hydrolysis. Above pH 7 the rate increases with pH. What kind of change is this?

![Chemical structure](image)

**Purpose of the problem**

Time for you to try your skill at interpreting pH-rate profiles.

**Suggested solution**

The second part of the question is easily dealt with. In alkaline solution the rate of hydrolysis simply increases with pH and we have the normal specific base-catalysed reaction in which hydroxide ion attacks the carbonyl group.

![Chemical structure](image)

But this is no ordinary ester. The leaving group is a thiol ($pK_a$ about 8) not the usual alcohol ($pK_a$ about 16) and so the thiolate anion is a much better leaving group than $\text{EtO}^-$. Also the CF$_3$ group is very electron-withdrawing so...
nucleophilic attack on the carbonyl group will be unusually fast. This is why there is a region of pH-independent hydrolysis not found with EtOAc. You might have suggested that acetate is a nucleophile or a general base catalyst but the solvent deuterium isotope effect suggests that it is a general base. The change at pH 7 is a change of mechanism as the faster of two mechanisms applies—a sketch of the pH-rate profile will show you the upward curve.

PROBLEM 5
In acid solution, the hydrolysis of this carbodiimide has a Hammett ρ value of –0.8. What mechanism might account for this?

Purpose of the problem
Interpretation of a small Hammett ρ value.

Suggested solution
The most obvious explanation for a low Hammett ρ value, that the aromatic ring is too far away from the reaction, will not wash here as the aromatic rings are joined directly to the reacting nitrogen atoms of the carbodiimide. The reaction must surely start with the protonation of one of the nitrogens. This cannot be the slow step and it would in any case have a large negative ρ value. The small ρ value observed suggests that the rate-determining step must have a large positive ρ value that nearly cancels out the large negative value for the first step. Attack by water on the protonated carbodiimide looks about right.
The expected equilibrium Hammett $\rho$ value for the protonation would be about $-2.5$ to $-3$ so the kinetic Hammett $\rho$ value for the attack of water would have to be about $+2$ to give a net Hammett $\rho$ value of $-0.8$. This looks fine. The rest of the mechanism involves proton transfers, hydrolysis of an imide, and decarboxylation.

**PROBLEM 6**

Explain the difference between these Hammett $\rho$ values by mechanisms for the two reactions. In both cases the ring marked with the substituent $X$ is varied. When $R = H$, $\rho = -0.3$ but when $R = \text{Ph}$, $\rho = -5.1$.

**Purpose of the problem**

Interpretation of a variation in Hammett $\rho$ value with another structural variation.

**Suggested solution**

The reaction is obviously nucleophilic substitution at the benzylic centre so we are immediately expecting $S_N1$ or $S_N2$. When $R = H$, the reaction occurs at a primary alkyl group and $S_N2$ is expected. When $R = \text{Ph}$, the reaction occurs at a secondary benzylic centre and $S_N1$ is expected.

The hydrolysis of carbodiimides in acid and base was studied by S. Hünig et al., *Liebigs Annalen*, 1953, 579, 87.
Since $S_N1$ produces a cation delocalized round the benzene ring in the slow step, a large negative Hammett $\rho$ value is reasonable. It is not obvious what sign the Hammett $\rho$ value would have in the $S_N2$ reaction but as there is no build-up of negative charge on the carbon atom in the transition state, a small value is reasonable. The actual value (−0.3) is very small indeed but, if we can read anything into it, it suggests a loose $S_N2$ transition state with a small positive charge on carbon.

**PROBLEM 7**

Explain how chloride catalyses this reaction.

**Purpose of the problem**

An extreme example of surprising catalysis.

**Suggested solution**

At first you might ask how chloride can catalyse anything at all. It is a weak base and not a very good nucleophile for the carbonyl group. However, in polar aprotic solvents like acetonitrile (MeCN), chloride is not solvated and is both more basic and more nucleophilic. In this reaction it cannot be a nucleophilic catalyst as attack on the carbonyl group simply regenerates...
starting material. It cannot be a specific base as it is too weak, even in acetonitrile, to remove a proton from methanol. But it can act as a general base. As methanol attacks the carbonyl group its proton becomes more acidic and, in the transition state, chloride is at last able to act.

PROBLEM 8

The hydrolysis of this oxaziridine in 0.1M sulfuric acid has \( k(H_2O)/k(D_2O) = 0.7 \) and an entropy of activation of \( \Delta S = -76 \text{ J mol}^{-1} \text{ K}^{-1} \). Suggest a mechanism.

Purpose of the problem

Deducing a mechanism from isotope effects and entropy of activation.

Suggested solution

The inverse solvent deuterium isotope effect indicates specific acid catalysis and the modest negative entropy of activation suggests some bimolecular involvement. There are various mechanisms you might have proposed and a likely one involves cleavage of the three-membered ring in the protonated amine. The second or possibly the third step could be rate-determining.

Once the three-membered ring is opened, the rest of the mechanism amounts to acid-catalysed hemiacetal hydrolysis. The original workers favoured an alternative mechanism that starts with protonation of the
oxygen atom and ends up with the hydrolysis of an imine. Again, the second or third step could be rate-determining.

PROBLEM 9
Explain how both methyl groups in the product of this reaction come to be labelled. If the starting material is reisolated at 50% reaction, its methyl group is also labelled.

Purpose of the problem
Exploring a mechanism through labelling.

Suggested solution
The role of silver ion (Ag⁺) is the removal of the halide to give an acylium ion that reacts, not at the carbonyl group, but at the methyl group to give CO₂ and a methylated benzene ring. The simple Friedel-Crafts route cannot be the whole story: it explains how the added methyl group is labelled, but not why it is only partly labelled and how label gets into the other methyl group.

The only way in which we can explain those extra features is to suggest that methylation initially occurs on the oxygen atom and that a methyl group is transferred from there to the benzene ring. We should never have
detected this detail without the labelling experiment. Alkylation on oxygen provides an alkylating agent that can transfer either CH₃ or CD₃ and also explains the formation of trideuterotoluene.

PROBLEM 10

The pKₐ values of some protonated pyridines are as follows:

<table>
<thead>
<tr>
<th>X</th>
<th>H</th>
<th>3-Cl</th>
<th>3-Me</th>
<th>4-Me</th>
<th>3-MeO</th>
<th>4-MeO</th>
<th>3-NO₂</th>
</tr>
</thead>
<tbody>
<tr>
<td>pKₐ</td>
<td>5.2</td>
<td>2.84</td>
<td>5.68</td>
<td>6.02</td>
<td>4.88</td>
<td>6.62</td>
<td>0.81</td>
</tr>
</tbody>
</table>

Can the Hammett correlation be applied to pyridines using the σ values for benzene? What equilibrium ρ value does it give and how do you interpret it? Why are no 2-substituted pyridines included in the list?

**Purpose of the problem**

Making sure you understand the ideas behind the Hammett relationship.

**Suggested solution**

The obvious thing to do is to plot the pKₐ values against the σ values for the substituents using the *meta* values for the 3-substituted and *para* values for the 4-substituted compounds (see table on p. 1042 of the textbook). This gives quite a good straight line and we get a slope (Hammett ρ value) of +5.9. The sign is of course positive as the same electronic effects that make benzoic acids more acidic will also make pyridinium ions more acidic. The large ρ value may have surprised you, but reflect: ionization of benzoic acids occurs outside the ring and the charge isn’t delocalized round the ring. Deprotonation of pyridinium ions occurs on the ring and the charge (positive this time) is delocalized round the ring.
There are no 2-substituted pyridines on the list since, like ortho-substituted benzenes, they cannot be expected to give a good correlation because of steric effects.

**PROBLEM 11**

These two reactions of diazo compounds with carboxylic acids give gaseous nitrogen and esters as products. In both cases the rate of reaction is proportional to [diazo compound][RCO₂H]. Use the data for each reaction to suggest mechanisms and comment on the difference between them.

\[
\begin{align*}
\text{Ar} & \quad \text{N} & \quad \text{RCO₂H} & \quad \text{Ar} \\
\text{Ar} & \quad \text{N} & \quad \text{O} & \quad \text{R} & \quad + \text{N}_2
\end{align*}
\]

\[
\begin{align*}
\rho = 1.6 \\
\frac{k(\text{RCO}_2\text{H})}{k(\text{RCO}_2\text{D})} = 3.5
\end{align*}
\]

\[
\begin{align*}
\text{EtO}_2\text{C} & \quad \text{N} & \quad \text{RCO₂H} & \quad \text{EtO}_2\text{C} \\
\text{EtO}_2\text{C} & \quad \text{N} & \quad \text{O} & \quad \text{R} & \quad + \text{N}_2
\end{align*}
\]

\[
\begin{align*}
\frac{k(\text{RCO}_2\text{D})}{k(\text{RCO}_2\text{H})} = 2.9
\end{align*}
\]

**Purpose of the problem**

Application of contrasting isotope effects to detailed mechanistic analysis.

**Suggested solution**

The first reaction has a normal kinetic isotope effect (RCO₂H reacts faster than RCO₂D) while the second has an inverse deuterium isotope effect (RCO₂H reacts slower than RCO₂D). This suggests that there is a rate-determining proton transfer in the first reaction but specific acid catalysis in the second (i.e. fast equilibrium proton transfer followed by slow reaction of the protonated species). Protonation occurs at carbon in both reactions, and this can be a slow step.
The second reaction follows much the same pathway except that loss of nitrogen is now difficult because the cation would be very unstable (primary and next to a CO₂Et group) so the second step is S₈2 and rate determining.

PROBLEM 12
Suggest mechanisms for these reactions and comment on their relevance to the Favorskii family of mechanisms.

Purpose of the problem
Extension of a section of the chapter (pp. 1061–3 of the textbook) into new reactions with internal trapping of intermediates.

Suggested solution
In the first reaction the bromination must occur on the alkene to give a dibromide. We cannot suggest stereochemistry at this stage and it is better to continue with the standard Favorskii mechanism and see what happens. Everything follows until the very last step when the opening of the cyclopropane provides electrons in just the right place to eliminate the second bromide and put the alkene back where it was. This alternative
behaviour of a proposed intermediate gives us confidence that the intermediate really is involved.

The stereochemistry of the initial bromination turns out to be irrelevant as it disappears when the oxyallyl cation is formed. We know the stereochemistry of the final product so we know the stereochemistry of the cyclopropanone: it must be on the opposite face of the five-membered ring to the methyl group. The disrotatory closure of the oxyallyl cation evidently goes preferentially one way with the H and the CMe₂Br substituents going upwards and the carbonyl group going down.

The second reaction to the right is a normal Favorskii. The only point of interest is the way the three-membered ring breaks up. The more stable carbanion is the doubly benzylic one so that leaves.

The reaction with excess bromoketone starts the same way but the oxyallyl cation is intercepted by one of the benzene rings in a four-electron conrotatory electrocyclic reaction like the Nazarov reaction (p. 927 of the textbook).
You may wonder how excess MeO\(^{-}\) stops this from happening. It doesn’t. The oxyallyl cation and the cyclopropanone are in equilibrium and excess MeO\(^{-}\) captures the cyclopropanone and drives the normal Favorskii onwards. If there is no excess MeO\(^{-}\) the oxyallyl cation lasts long enough for the five-membered ring to be the main product.

**PROBLEM 13**

A typical Darzens reaction involves the base-catalysed formation of an epoxide from an \(\alpha\)-haloketone and an aldehyde. Suggest a mechanism consistent with the data below.

![Chemical structure](https://example.com/structure.png)

(a) The rate expression is: rate = \(k[\text{PhCOCH}_2\text{Cl}][\text{ArCHO}][\text{EtO}^-]\)

(b) When Ar is varied, the Hammett \(\rho\) value is +2.5.

(c) The following attempted Darzens reactions produced unexpected results:

![Chemical structure](https://example.com/structure2.png)

**Purpose of the problem**

Trying to get a complete picture of a reaction using physical data and structural variation.

**Suggested solution**

The ethoxide is not incorporated into the product but appears in the rate expression. Its role must be as a base and there is only one set of enolizable protons. We start by making the enolate of the chloroketone. This cannot be the slow step as the aldehyde appears in the rate expression. Then we can

---

This work was part of a thorough investigation into the mechanism of the Favorskii rearrangement by F. G. Bordwell and group, *J. Am. Chem. Soc.*, 1970, 92, 2172.
attack the aldehyde with the enolate and finally close the epoxide ring by nucleophilic displacement of chloride ion.

If this mechanism is right, the kinetic data show that the second step is rate-determining (a reasonable deduction as it is a bimolecular step) and that the first step is a pre-equilibrium. We can write:

\[
\text{rate} = k_2[\text{enolate}][\text{ArCHO}]
\]

And we know from the pre-equilibrium that

\[
K_1 = \frac{[\text{enolate}]}{[\text{PhCOCH}_2\text{Cl}][\text{EtO}^-]}
\]

So the rate expression becomes when we substitute for [enolate]:

\[
\text{rate} = K_1 k_2[\text{PhCOCH}_2\text{Cl}][\text{EtO}^-][\text{ArCHO}]
\]

and this matches the observed rate expression though the apparently third order rate constant is revealed as the product of an equilibrium constant and a second order rate constant.

The Hammett \( \rho \) value shows a modest gain of electrons near the Ar group in the rate-determining step. We must not take the pre-equilibrium into account as ArCHO is not involved in this step. In fact a Hammett \( \rho \) value of +2.5 is typical of nucleophilic attack on a carbonyl group conjugated to the benzene ring.

The unexpected products come from variations in this mechanism. para-Methoxybenzaldehyde is conjugated and unreactive so the enolate ignores it and reacts with the unenolized version of itself.

With salicylaldehyde, the second example, the phenolic OH group will exist as an anion under the reaction conditions. Alkylation by the
chloroketone allows enolate formation leading to an intramolecular aldol reaction.

PROBLEM 14
If you believed that this reaction went by elimination followed by conjugate addition, what experiments would you carry out to try and prove that the enone is an intermediate?

Purpose of the problem
Turning the usual question backwards: what evidence do you want, rather than how to interpret what you are given.

Suggested solution
The suggested mechanism of elimination followed by conjugate addition might be contrasted with direct $S_{N}2$ to see what evidence is needed.
There are many types of evidence you might suggest: here are some of them.

- Exchange of protons in D$_2$O/EtOD would suggest elimination/addition.
- Kinetic evidence (tricky as you cannot be sure which is the slow step.
- A Hammett plot with substituted benzene rings. The $S_N$2 mechanism would have a small $\rho$ as the benzene ring is a long way from the action.
- Base catalysis: mechanism 2 is base catalysed, mechanism 1 isn’t.
- Kinetic isotope effect might be found in mechanism 2.
- Stereochemistry. If a substituent were added to make the terminal carbon chiral, inversion would be expected for mechanism 1 and racemization for mechanism 2. But choose a small substituent otherwise it would be a very different compound.
Suggested solutions for Chapter 40

**PROBLEM 1**
Suggest mechanisms for these reactions, explaining the role of palladium in the first step.

![Chemical structures and reactions diagram]

**Purpose of the problem**
Revision of enol ethers and bromination, the Wittig reaction, and, of course, first steps in palladium chemistry.

**Suggested solution**
The first step is a reaction of an enol with an allylic acetate catalysed by palladium(0) via an \( \eta^3 \) allyl cation. There is no regiochemistry to worry about as the diketone and allylic acetate are both symmetrical.

![Chemical structures and reactions diagram]

NBS in aqueous solution is a polar brominating agent, ideal for reaction with an enol ether. The intermediate is hydrolysed to the ketone by the usual acetal style mechanism.

You might have drawn the \( \eta^3 \) allyl cation complex in various satisfactory ways—some are mentioned on p. 1089 of the textbook.
Finally, an intramolecular Wittig reaction. This is a slightly unusual way to do what amounts to an aldol reaction but the 5,5 fused enone system is strained and the Wittig went under very mild conditions (\(\text{K}_2\text{CO}_3\) in aqueous solution). The stereochemistry of the new double bond is the only one possible and Wittig reactions with stabilized ylids generally give the most stable of the possible alkene.

PROBLEM 2
This Heck-style reaction does not lead to regeneration of the alkene. Why not? What is the purpose of the formic acid (\(\text{HCO}_2\text{H}\)) in the reaction mixture?

**Purpose of the problem**
Making sure you understand the steps in the mechanism of the Heck reaction.

**Suggested solution**
The reaction must start with the oxidative addition of Pd(0) into the Ph–I bond. The reagent added is Pd(II) so one of the reduction methods on page 1081 of the textbook must provide enough Pd(0) to start the reaction going. The oxidative addition gives PhPdI and this does the Heck reaction on the alkene. Addition occurs on the less hindered top (\(\text{exo}\)) face and the phenyl group is transferred to the same face.
Normally now the alkyl palladium(II) species would lose palladium by $\beta$-elimination. This is impossible in this example as there is no hydrogen atom syn to the PdI group. Instead, an external reducing agent is needed and that is the role of the formate anion: it provides a hydride equivalent by ‘transfer hydrogenation’ when it loses CO$_2$.

**PROBLEM 3**
Cyclization of this unsaturated amine with catalytic Pd(II) under an atmosphere of oxygen gives a cyclic unsaturated amine in 95% yield. How does the reaction work? Why is the atmosphere of oxygen necessary? Explain the stereochemistry and regiochemistry of the reaction. How would you remove the CO$_2$Bn group from the product?

**Purpose of the problem**
Introducing you to ‘aminopalladation’: like oxypalladation, nucleophilic attack on a palladium $\pi$-complex.

**Suggested solution**
The $\pi$-complex between the alkene and Pd(II) permits nucleophilic attack by the amide on its nearer end and in a cis fashion because the nucleophile is tethered by a short chain of only two carbon atoms. Nucleophilic attack and elimination of Pd(0) occur in the usual way. The removal of the CO$_2$Bn group would normally be done by hydrogenolysis but in this case ester hydrolysis by, say, HBr would be preferred to avoid reduction of the alkene. The free acid decarboxylates spontaneously.
This general synthesis of heterocycles was introduced by J.-E. Bäckvall and group, *Tetrahedron Lett.*, 1995, **36**, 7749.

**PROBLEM 4**

Suggest a mechanism for this lactone synthesis.

Purpose of the problem

Introducing you to carbonyl insertion into a palladium (II) σ-complex.

Suggested solution

Oxidative insertion into the aryl bromide, carbonylation, and nucleophilic attack on the carbonyl group with elimination of Pd(0) form the catalytic cycle. No doubt the palladium has a number (1 or 2?) of phosphine ligands complexed to it during the reaction and these keep the Pd(0) in solution between cycles.

* M. Moru *et al.*, *Heterocycles*, 1979, **12**, 921.
PROBLEM 5
Explain why enantiomerically pure lactone gives syn but racemic product in this palladium-catalysed reaction.

Purpose of the problem
Helping you to understand the details of palladium-catalysed allylation.

Suggested solution
Following the usual mechanism, the palladium complexes to the face of the alkene opposite the bridge. The ester leaves to give an allyl cation complex. This is attacked by the malonate anion from the opposite face to the palladium. So the overall result is retention of configuration, the syn starting material giving the syn product.

The racemization comes from the structure of the allyl cation complex. It is symmetrical with a plane of symmetry running vertically through the complex as drawn. Attack by the malonate anion occurs equally at either side of the plane giving the two enantiomers of the syn diasterereoisomer in equal amounts.

**PROBLEM 6**

Explain the reactions in this sequence, commenting on the regioselectivity of the organometallic steps.

![Chemical Reaction Diagram]

**Purpose of the problem**

Revision of allylic Grignard reagents, the synthesis of pyridines, and the mechanism of the Wacker oxidation.

**Suggested solution**

The allylic Grignard reagent does direct addition from the end remote to the magnesium atom, as often happens. Hydrolysis of the silyl enol ether reveals an aldehyde.

![Chemical Reaction Diagram]

Now the Wacker oxidation, by whatever detailed mechanism you prefer, must involve the addition of water to a Pd(II) π-complex of the alkene and β-elimination of palladium to give Pd(0) which is recycled by oxidation with oxygen mediated by copper.
Finally, the pyridine synthesis is simply a double enamine/imine formation between ammonia and the two carbonyl groups. Probably the aldehyde reacts first.

**PROBLEM 7**

Give a mechanism for this carbonylation reaction. Comment on the stereochemistry and explain why the yield is higher if the reaction is carried out under a carbon monoxide atmosphere.

Hence explain this synthesis of part of the antifungal compound pyrenophorin.

**Purpose of the problem**

More carbonylation with a Stille coupling.
Suggested solution

The tin-palladium exchange (transmetallation) occurs with retention of configuration at the alkene. The exchange of the benzyl group for the benzoyl group is necessary to get the reaction started.

\[
\text{Bu}_3\text{Sn} + \text{Ph}_3\text{P-Pd-Cl} \rightarrow \text{Ph}_3\text{P-Pd-CH}_2\text{Ph} + \text{Bu}_3\text{Sn-Cl}
\]

\[
\text{Ph}_3\text{P-Pd-Cl} + \text{PhCOCl} \rightarrow \text{Ph}_3\text{P-Pd-Cl-PhCO} + \text{PhCH}_2\text{Cl}
\]

Now the coupling can take place on the palladium atom producing the product and Pd(0) which can insert oxidatively into the C–Cl bond. Transmetallation sets up a sustainable cycle of reactions. It is better to have an atmosphere of carbon monoxide because the acyl palladium complex can give off CO and leave a PdPh σ-complex. The atmosphere of CO reverses this reaction.

\[
\text{Ph}_3\text{P-Pd-Cl-PhCO} \rightarrow \text{Ph}_3\text{P-Pd-Cl} + \text{PhCO}
\]

\[
\text{Ph}_3\text{P-Pd-Cl-PhCO} + \text{Bu}_3\text{Sn} \rightarrow \text{Ph}_3\text{P-Pd-Cl} + \text{PhCH}_2\text{Cl}
\]

The second sequence starts with a radical hydrostannylation (chapter 37) giving the E-vinyl stannane preferentially if a slight excess of Bu₃SnH is used.

\[
\text{Bu}_3\text{Sn} + \text{OBn} \rightarrow \text{Bu}_3\text{Sn-OBn}
\]

\[
\text{Bu}_3\text{Sn-OBn} \rightarrow \text{Bu}_3\text{Sn-CO}_2\text{Bn}
\]

Now the coupling with the acid chloride takes place as before though this time we have an aliphatic carbonyl complex. There is no problem with β-elimination as that would give a ketene. Again, the stereochemistry of the vinyl stannane is retained in the product.
PROBLEM 8
A synthesis of an antifungal drug made use of this palladium-catalysed reaction. Give a mechanism, explaining the regio- and stereochemistry.

Purpose of the problem
A simple example of amine synthesis using palladium.

Suggested solution
The palladium forms the usual allyl cation complex and the nitrogen nucleophile attacks the less hindered end thus also retaining the conjugation. Attack at the triple bond would give an allene. The $E$ stereochemistry of the palladium complex is retained in the product.
PROBLEM 9
Work out the structures of the compounds in this sequence and suggest mechanisms for the reactions, explaining any selectivity.

\[
\begin{array}{c}
\text{CHO} & \text{CHO} & \text{CHO} \\
\text{heat with} & \text{Pd(II)} & \text{KOH} \\
\text{catalytic acid} & \text{CuCl, O}_2 & \text{H}_2\text{O, THF} \\
\end{array}
\]

B has IR: 1730, 1710 cm\(^{-1}\), \(\delta_h\) 9.4 (1H, s), 2.6 (2H, s), 2.0 (3H, s), and 1.0 (6H, s).
C has IR: 1710 cm\(^{-1}\), \(\delta_h\) 7.3 (1H, d, \(J\ 5.5\ Hz\)), 6.8 (1H, d, \(J\ 5.5\ Hz\)), 2.1 (2H, s), and 1.15 (6H, s).

Purpose of the problem
An intramolecular aldol reaction (p. 636 of the textbook) and a Wacker oxidation (p. 1096 of the textbook).

Suggested solution
B clearly has aldehyde and ketone functional groups with nothing but singlets in the NMR. On the other hand C has a cis disubstituted alkene with a small (and therefore cis) \(J\) value and is a cyclopentenone.
**PROBLEM 10**

A synthesis of the Bristol-Myers Squibb anti-migraine drug Avitriptan (a 5-HT receptor antagonist) involves this palladium-catalysed indole synthesis. Suggest a mechanism and comment on the regioselectivity of the alkyne attachment.

---

**Purpose of the problem**

A new reaction for you to try— a palladium-catalysed indole synthesis.

**Suggested solution**

Although palladium(II) is added to the solution, the aryl iodide tells you that this is an oxidative insertion of Pd(0) produced by one of the methods described on p. 1081 of the textbook. The resulting Pd(II) species complexes to the alkyne and the amine can now attack the triple bond. This gives a heterocycle with the Pd(II) in the ring. Coupling of the two organic fragments extrudes Pd(0) to start a new cycle. The nitrogen attacks the more hindered end of the alkyne so that the palladium can occupy the less hindered end.
PROBLEM 1

Explain how this synthesis of amino acids, starting with natural proline, works. Explain the stereoselectivity of each step after the first.

Purpose of the problem

A simple exercise in the creation of a new stereogenic centre via a cyclic intermediate.

Suggested solution

Nothing exciting happens until the hydrogenation step. The stereoselectivity of the reaction with ammonia is interesting but not of any consequence as that stereochemistry disappears in the elimination. This gives the $E$-enone as expected since the alkene and the carbonyl group are in the same plane.

The new stereogenic centre is created in the hydrogenation step. The molecule is slightly folded and the catalyst interacts best with the outside (convex) face so that it adds hydrogen from the same face as the ring junction hydrogen. All that remains is to hydrolyse the product without racemization. Did you notice that the configuration of the new amino acid (S) is the same as that of the natural amino acids?

**PROBLEM 2**

This is a synthesis of the racemic drug tazodolene. If the enantiomers of the drug are to be evaluated for biological activity, they must be separated. At which stage would you recommend separating the enantiomers and how would you do it?

**Purpose of the problem**

First steps in planning an asymmetric synthesis by resolution.

**Suggested solution**

You need to ask: which is the first chiral intermediate? Can it be conveniently resolved? Will the chirality survive subsequent steps? The first
intermediate is chiral but it enolizes very readily and the enol is achiral, so that’s no good. The second intermediate is chiral but it has three chiral centres and these are evidently not controlled. We would have to separate the diastereoisomers before resolution and that would be a waste of time and material since all of them give the next intermediate anyway.

The next intermediate, the amino alcohol is ideal: it has only one chiral centre and that is not affected by the last reaction. It has two ‘handles’ for resolution—the amine and the alcohol. We might make a salt with tartaric acid or an ester of the alcohol with some chiral acid. Alternatively we could resolve tazadolene itself: it still has an amino group and we could form a salt with a suitable acid.

**PROBLEM 3**

How would you make enantiomerically enriched samples of these compounds (either enantiomer)?

**Purpose of the problem**

First steps in planning an asymmetric synthesis.

**Suggested solution**

There are many possible answers here. What we had in mind was some sort of asymmetric Diels-Alder reaction for the first, an asymmetric aldol for the second or else opening an epoxide made by Sharpless epoxidation, asymmetric dihydroxylation for the third, and perhaps asymmetric dihydroxylation of a Z-alkene for the fourth. Of course you might have used resolution or asymmetric hydrogenation, or the chiral pool, or any other strategy from chapter 41.
PROBLEM 4

In the following reaction sequence, the stereochemistry of mandelic acid is transmitted to a new hydroxy-acid by stereochemically controlled reactions. Give mechanisms for each reaction and state whether it is stereospecific or stereoselective. Offer some rationalization for the creation of new stereogenic centres in the first and last reactions.

Purpose of the problem

Your chance to examine an ingenious method of asymmetric induction.

Suggested solution

The first reaction amounts to cyclic acetal formation except that one of the 'alcohols' is a carboxylic acid. The reaction is stereospecific (no change) at the original chiral centre and stereoselective at the new one.
The second reaction creates a lithium enolate and alkylates it. It is again stereospecific at the unchanged chiral centre and stereoselective at the new one. Finally, acetal hydrolysis preserves the new quaternary centre unchanged (stereospecific) by a mechanism that is the reverse of the first step.

Now, as far as the rationalization is concerned, the first step takes place through a sequence of reversible reactions and therefore under thermodynamic control so the most stable product will be formed. It may seem surprising that this should be the cis compound, but the conformation of this chair-like five-membered ring prefers to have the two substituents pseudoequatorial.

The alkylation is under kinetic control and, as a lithium enolate has more or less a flat ring, the alkyl halide approaches the opposite face to the t-Bu group. It has to approach orthogonally to the ring as it must overlap with the p orbital of the enolate.

This is Seebach's clever method of preserving the knowledge of a chiral centre while it is destroyed in a reaction. First a temporary centre (at the t-buty1 group) is created in a stereoselective reaction; the original centre is destroyed by enolization but the temporary centre can be used to re-create it: D. Seebach et al., J. Am. Chem. Soc., 1983, 105, 5390.
PROBLEM 5
This reaction sequence can be used to make enantiomerically enriched amino acids. Which compound is the origin of the chirality and how is it made? Suggest why this particular enantiomer of the product amino acid might be formed. Suggest reagents for the last stages of the process. Would the enantiomerically enriched starting material be recovered?

Purpose of the problem
Step-by-step discussion of a simple but useful sequence.

Suggested solution
The amine, phenylethylamine, is the origin of the chirality. It is easily made by resolution, for example by crystallizing the salt of the racemic amine with tartaric acid. This means that both enantiomers are readily available.

This particular enantiomer of the amino acid product belongs to the natural (S) series. The unnatural (R) enantiomer would also be valuable and can be made from the other enantiomer of the starting material. The last stages of the process require cleavage of one C–N bond and hydrolysis of the nitrile. It will be important to do this without racemizing the newly created centre.

The C–N bond can be cleaved reductively by hydrogenation as it is an N-benzyl bond. This would also hydrogenate the nitrile so that must first be
hydrolysed using acid or base, as weak as possible. The starting material is not recovered and the chirality is lost as the by-product is just ethyl benzene, the nitrogen atom being transferred to the product.

PROBLEM 6
Explain the stereochemistry and mechanism in the synthesis of the chiral auxiliary 8-phenylmenthol from (+)-pulegone. After the reaction with Na in i-PrOH, what is the minor (13%) component of the mixture?

Purpose of the problem
A combination of conformational analysis, stereoselective reactions, and resolution to get a single enantiomer.

Suggested solution
The first reaction is a conjugate addition that evidently goes without any worthwhile stereoselectivity. The stereochemistry is not fixed in the addition but in the protonation of the enolate in the work-up. Equilibration of the mixture by reversible enolate formation with KOH in ethanol gives mostly the all-equatorial compound.
Reduction by that smallest of reagents, an electron, gives the all-equatorial product. Since the stereochemical ratio in the product is the same as in the starting materials (87:13), the reduction must be totally stereoselective. The all-equatorial ketone gives 100% all-equatorial alcohol and the minor isomer must give one other diastereoisomer (we cannot say which).

The mixture still has to be separated and, as it is a mixture of diastereoisomers, it can be separated by physical means. The chloroacetate is just a convenient crystalline derivative.

**PROBLEM 7**
Suggest syntheses for single enantiomers of these compounds.

**Purpose of the problem**
Devising your own asymmetric syntheses.

**Suggested solution**
The first compound is an ester derived from a cyclic secondary alcohol that could be made from the corresponding enone by asymmetric reduction.
Reduction with Corey’s CBS reducing agent gave the alcohol in 93% ee.

The second compound could be made by a Wittig reaction with a stabilized ylid and the required diol aldehyde derived from an epoxy-alcohol and hence an allylic alcohol by Sharpless epoxidation.

The first part of the synthesis gives an intermediate that had been used in the synthesis of the antibiotic methymycin. In practice the Wittig was carried out on the epoxy-aldehyde and treatment of the last intermediate with aqueous acid gave the target molecule.

This compound was used to make a compound from the gingko tree by E. J. Corey and A. V. Gaval, Tetrahedron Lett., 1988, 29, 3201.

S. Masamune et al., J. Am. Chem. Soc. 1975, 97, 3512
PROBLEM 8
This compound is a precursor to a Novartis drug used for the control of inflammation. How might it be made from a chiral pool starting material?

Purpose of the problem
Spotting in a target structural features of available chiral pool compounds.

Suggested solution
The hydrocarbon skeleton of the target is that of the amino acid phenylalanine. The configuration is \((S)\), the same as the natural amino acid, so we can use the standard amino acid to hydroxy acid conversion via diazotization, described on p. 1105 of the textbook, which goes with retention of configuration. The aromatic ring needs hydrogenating too.

L-phenylalanine
PROBLEM 9
Propose catalytic methods for the asymmetric synthesis of these four precursors to drug molecules.

\[ \begin{align*}
\text{propose catalytic methods for the asymmetric synthesis of these four precursors to drug molecules.}
\end{align*} \]

Purpose of the problem
Identifying reliable catalytic reactions that give desired structural features.

Suggested solution
The sertraline precursor is a chiral alcohol with the stereogenic centre adjacent to an aromatic ring. An obvious approach is to make the hydroxyl group by asymmetric reduction of the corresponding ketone. CBS reduction is a possibility, as is a ruthenium-catalysed hydrogenation using the ligand TsDPEN (p. 1115 of the textbook).

The second compound is a chiral sulfide. Although there are direct asymmetric ways of making chiral sulfur compounds, a reliable approach to sulfides is to use S$_2$2 substitution of a more readily made chiral precursor, because a thiolate is usually a good nucleophile. The S$_2$2 reaction goes with inversion, so we need the chiral alcohol shown below, converted to a derivative (such as a tosylate) capable of undergoing substitution. Care will be needed to avoid elimination, but thiolates are excellent nucleophiles and not too basic, so you would expect a successful outcome.

- You should not try to remember which enantiomer of the ligand you need for which enantiomer of the product: that can easily be looked up later. It is much more important to recognize the classes of molecules that can be reliably prepared by catalytic asymmetric reactions.
The third compound contains a 1,2,3-trifunctionalized arrangement that should prompt you to think of asymmetric epoxidation. Azide is a good nucleophile for opening epoxides, so we can start with the allylic alcohol shown here, carry out an asymmetric epoxidation, and convert to the target with inversion of configuration.

The final compound is a diol, so asymmetric dihydroxylation is a possible approach. The precursor is a rather unreactive alkene, but asymmetric dihydroxylation is a versatile reaction which can still perform well on challenging substrates.

**PROBLEM 10**

The triatomine bug which causes Chagas’ disease can be trapped by using synthetic samples of its communication pheromone, which consists of a 4:1 mixture of the enantiomers of this heterocycle. How would you synthesize the required mixture of enantiomers? Why would the other diastereoisomer of this compound be more of a challenge to make?

**Purpose of the problem**

Identifying structural features that can be made by asymmetric synthesis.
Suggested solution

To make a 4:1 mixture of enantiomers you need either to mix them in the right proportions, or to mix equal amounts of racemic mixture and a single enantiomer. In either case you need an asymmetric synthesis. The target compound is an acetal that can be made from a chiral diol, so you should immediately consider asymmetric dihydroxylation. The advantage of Sharpless’ asymmetric dihydroxylation is that it can very easily give either enantiomer: in fact, it is one reaction where the enantioselective version is better than the racemic one, so you would be advised to make the two enantiomers using the two alternative chiral ligands, mix them in the correct proportions, then form the acetal. Note that the starting alkene is trans.

\[
\begin{align*}
\text{K}_3\text{Fe(CN)}_6 & \\
\text{DHQ}_2\text{PHAL} \quad \text{(or DHQD}_2\text{PHAL for other enantiomer)} & \\
\text{K}_2\text{OsO}_2(OH)_4 & \\
\text{K}_2\text{CO}_3, \quad \text{MeSO}_2\text{NH}_2 & \\
\text{H}^+ \text{ cat.} & \\
\end{align*}
\]

Making the other diastereoisomer would require the cis alkene. This is not a problem in itself, but more of a challenge for the catalyst, because now it has to distinguish between two similar groups (Et and Me) in order to oxidize one face of the alkene enantioselectively (for the trans alkene, the selection is between either Et and H or Me and H; switching Et for Me makes no difference to the outcome).

The discovery and synthesis of this pheromone is described by C. R. Unelius and co-workers in *Org. Lett.* 2010, **12**, 5601.
**PROBLEM 11**

This compound was developed by the Nutrasweet company as an artificial sweetener. Propose a strategy for its synthesis. Would your proposed approach still be suitable if the compound had turned out to be a successful product, required in multi-tonne quantities?

![Chemical Structure]

**Purpose of the problem**

Proposing an efficient synthetic route to a chiral target molecule: a common challenge in the pharmaceutical and related industries.

**Suggested solution**

The target can be best disconnected into three fragments at the amide bonds. The aminopyridine can be made by the standard methods of heterocycle synthesis (chapter 30), so we are more interested in the other two chiral fragments. The middle one is an amino acid, and you should recognize it as a member of the chiral pool, (S)-glutamic acid, so this poses no problem of synthesis. (Though it will need to be appropriately protected to form the correct amide).

![Disconnected Structures]

The final fragment is a simple chiral carboxylic acid, so we need a method for its asymmetric synthesis. The most obvious choice is probably an asymmetric alkylation using Evans’ oxazolidinone auxiliary: formation of the appropriate derivative of hexanoic acid is simple, and the enolate will be alkylated diastereoselectively by methyl iodide. You would probably take this approach if you need to make a few grams for initial studies.
If this compound were needed on the tonne scale then auxiliary chemistry is no good, however efficient recycling may be. A good alternative for the synthesis of compounds with unfunctionalized chiral centres adjacent to carboxylic acids or alcohols is the use of ruthenium-catalysed hydrogenation.

PROBLEM 12

The two aldehydes below are valuable products in the perfumery industry (Tropional® is a component of Issey Miyake’s L’Eau d’Issey and Florhydral® is a component of Allure by Chanel). How would you make them as single enantiomers?

Purpose of the problem

Designing a synthesis where absolute stereochemistry must be controlled.

Suggested solution

Both targets have a single, simple chiral centre carrying a methyl group, so we need to devise a synthesis passing through an achiral precursor. For Tropional, you might imagine alkylating a derivative of Evans’ auxiliary, followed by reduction to the aldehyde, but a more economical approach would be to use asymmetric reduction of an unsaturated carboxylic acid, since the compound required is readily made using an aldol-type condensation of the available aldehyde piperonal.
Florhydral has the methyl group β to the aldehyde. One possible approach is an asymmetric conjugate addition, but again asymmetric reduction of the acid (or allylic alcohol) is preferable, since the required alkene is easy to make by aldol chemistry. Here we show one example with the acid and one with the alcohol, but either are possibilities in both cases.
**Suggested solutions for Chapter 42**

**PROBLEM 1**
Do you consider that thymine and caffeine are aromatic compounds? Explain.

![Thymine and Caffeine Structures](image)

**Purpose of the problem**
Revision of aromaticity and exploration of the structures of nucleic acid bases.

**Suggested solution**
Thymine, a pyrimidine, has an alkene and lone pair electrons on two nitrogens, making six in all for an aromatic structure. You may have shown this by drawing delocalized structures.

![Thymine Delocalization Structures](image)

Caffeine, a purine, is slightly more complicated as it has two rings. You might have said that each ring is aromatic if you counted all the lone pairs on nitrogen except those on the ‘pyridine-like’ nitrogen (see p. 741 of the textbook for what we mean here) in the five-membered ring. Or you might have drawn a delocalized structure with ten electrons around its periphery.
PROBLEM 2

Human hair is a good source of cystine, the disulfide dimer of cysteine. Hair is boiled with aqueous HCl and HCO₂H for a day, the solution concentrated, and a large amount of sodium acetate added. About 5% of the hair by weight crystallizes out as pure cystine \([\alpha]_D = -216\). How does the process work? Why is such a high proportion of hair cystine? Why is no cysteine isolated by this process? Make a drawing of cystine to show why it is chiral. How would you convert the cystine to cysteine?

Suggested solution

Prolonged boiling with HCl hydrolyses the peptide linkages (shown as thick bonds below in a generalized structure) and breaks the hair down into its constituent amino acids. The cystine crystallizes at neutral pHs and the mixture of HCl and NaOAc provides a buffer. Hair is much cross-linked by disulfide bridges and these are not broken down by hydrolysis.

Purpose of the problem

Some slightly more complicated amino acid chemistry including stereochemistry and the SH group.
No cysteine is isolated because (i) most of it is present as cystine in hair and (ii) any cysteine released in the hydrolysis will be oxidized in the air to cystine. The stereochemistry of cysteine is preserved in cystine which has $C_2$ symmetry and no plane or centre of symmetry so either of the diagrams below will suit. It is not important whether you draw the zwitterion or the uncharged structure. Reduction of the S–S bond by NaBH$_4$ converts cystine to cysteine.

\[
\begin{align*}
\text{O}_2\text{C} & \quad \text{S} \\
\quad & \quad \text{S} \\
\text{CO}_2 & \quad \text{NH}_3
\end{align*}
\quad
\begin{align*}
\text{OH}_2\text{C} & \quad \text{S} \\
\quad & \quad \text{S} \\
\text{NH}_2 & \quad \text{CO}_2\text{H}
\end{align*}
\]

**PROBLEM 3**

The amide of alanine can be resolved by pig kidney acylase. Which enantiomer of alanine is acylated faster with acetic anhydride? In the enzyme-catalysed hydrolysis, which enantiomer hydrolyses faster? In the separation, why is the mixture heated in acid solution, and what is filtered off? How does the separation of the free alanine by dissolution in ethanol work?

If the acylation is carried out carelessly, particularly if the heating is too long or too strong, a by-product is formed that is not hydrolysed by the enzyme. How does this happen?

\[
\begin{align*}
\text{NH}_2 & \quad \text{CO}_2\text{H} \\
racemic \text{alanine} & \quad \text{Ac}_2\text{O, AcOH}
\end{align*}
\quad
\begin{align*}
\text{HN} & \quad \text{O} \\
\text{pig kidney acylase} & \quad \text{pH 8, 37 °C, 4 hours}
\end{align*}
\]

**Purpose of the problem**

Rehearsal of some basic amino acid and enzyme chemistry plus revision of stereochemistry and asymmetric synthesis.
Suggested solution

The acylation takes place by the normal mechanism for the formation of amides from anhydrides, that is, by nucleophilic attack on the carbonyl group and loss of the most stable anion (acetate) from the tetrahedral intermediate. The two isomers of alanine are enantiomers and enantiomers must react at the same rate with achiral reagents.

\[
\begin{align*}
\text{CO}_2\text{H} & \quad \text{NH}_2 \\
\text{CO}_2\text{H} & \quad \text{H}_2\text{N}
\end{align*}
\]

In the enzyme-catalysed reaction, the acylase hydrolyses the amide of one enantiomer but not the other. This time the two enantiomers do not react at the same rate as the reagent (or catalyst if you prefer) is the single enantiomer of a large peptide. Not surprisingly, the enzyme cleaves the amide of natural alanine and leaves the other alone.

\[
\begin{align*}
\text{CO}_2\text{H} & \quad \text{HN} \\
\text{CO}_2\text{H} & \quad \text{NH}_2
\end{align*}
\]

The purification and separation first requires removal of the enzyme. This is soluble in pH 8 buffer but acidification and heating denature the enzyme (this is rather like what happens to egg white on heating) and destroy its structure. The solid material filtered off is this denatured enzyme. The separation in ethanol works because the very polar amino acid is soluble only in water but the amide is soluble in ethanol.

\[
\begin{align*}
\text{CO}_2\text{H} & \quad \text{HN} \\
\text{CO}_2\text{H} & \quad \text{NH}_2
\end{align*}
\]

Overheating the acid solution causes cyclization of the amide oxygen atom onto the carboxylic acid. This reaction happens only because the formation of a five-membered ring, an ‘azlactone’. These compounds are dreaded by chemists making peptides because they racemize easily by enolization (the enol is achiral).
PROBLEM 4
A patent discloses this method of making the anti-AIDS drug d4T. The first few stages involve differentiating the three hydroxyl groups of 5-methyluridine as we show below. Explain the reactions, especially the stereochemistry at the position of the bromine atom.

Suggest how the synthesis might be completed.

Purpose of the problem
A chance for you to explore nucleoside chemistry, particularly the remarkable control the heterocyclic base can exert over the stereochemistry of the sugar.

Suggested solution
There is a remarkable regio- and stereochemical control in this sequence. How are three OH groups converted into three different functional groups with retention of configuration? The first step must be the formation of the trimesylate. Then treatment with base brings the pyrimidine into play and
allows replacement of one mesylate by participation through a five-membered ring.

Now the weakly nucleophilic benzoate can replace the only primary mesylate and the participation process is brought to completion with HBr. Opening the ring gives a bromide with double inversion—that is, retention.

To complete the synthesis of the drug, some sort of elimination is needed, removing both Br and Ms in a syn fashion. You might do this in a number of ways probably by metellation of the bromide and loss of mesylate. It turns out that the two-electron donor zinc does this job well. Finally the benzoate protecting group must be removed. There are many ways to do this but butylamine was found to work well.
PROBLEM 5
How are phenyl glycosides formed from phenols (in nature or in the laboratory)?
Why is the configuration of the glycoside not related to that of the original sugar?

Purpose of the problem
Revision of the mechanism of acetal formation and the anomeric effect.

Suggested solution
The hemiacetal gives a locally planar oxonium ion that can add the phenol from the top or bottom face. The bottom face is preferred because of the anomeric effect and acetal formation is under thermodynamic control.

PROBLEM 6
‘Caustic soda’ (NaOH) was used to clean ovens and blocked drains. Many commercial products for these jobs still contain NaOH. Even concentrated sodium carbonate (Na₂CO₃) does quite a good job. How do these cleaners work? Why is NaOH so dangerous to humans especially if it gets into the eye?

Purpose of the problem
Relating the structure of fats to everyday things as well as to everyday chemical reactions.

Suggested solution
The grease in ovens and blockages in drains are generally caused by hard fats that solidify there. Fats are triesters of glycerol (p. 1148 of the textbook) and are hydrolysed by strong base giving liquid glycerol and the water-soluble sodium salts of the acids.
Sodium hydroxide is dangerous to humans because it not only hydrolysates esters but attacks proteins. It damages the skin and is particularly dangerous in the eyes as it quickly destroys the tissues there. Strong bases are more dangerous to us than are strong acids, though they are bad enough. The sodium salts from fats as well as glycerol are used in soaps.

**PROBLEM 7**

Draw all the keto and enol forms of ascorbic acid (the reduced form of vitamin C). Why is the one shown here the most stable?

**Purpose of the problem**

Revision of enols and an assessment of stability by conjugation.

**Suggested solution**

There can be two keto forms with one carbonyl group and two keto (or ester) forms with two carbonyl groups.

Two forms have greater conjugation than the other two and the favoured form preserves the ester rather than a ketone and so has extra conjugation.
PROBLEM 8

The amino acid cyanoalanine is found in leguminous plants (*Lathyrus* spp.) but not in proteins. It is made in the plant from cysteine and cyanide by a two-step process catalysed by pyridoxal phosphate. Suggest a mechanism. We suggest you use the shorthand form of pyridoxal phosphate shown here.

Purpose of the problem

Exploration of a new reaction in pyridoxal chemistry using pyridoxal itself rather than pyridoxamine.

Suggested solution

The reaction starts with the formation of the usual imine/enamine equilibrium but what looks like an $S_N2$ displacement of $\sim$SH by $\sim$CN turns out to be an elimination followed by a conjugate addition. Any attempt at an $S_N2$ displacement would simply remove the proton from the SH group. Notice that the pyridoxal is regenerated.
PROBLEM 9
Assign each of these natural products to a general class (such as amino acid metabolite, terpene, polyketide) explaining what makes you choose that class. Then assign them to a more specific part of the class (such as pyrrolidine alkaloid).

Purpose of the problem
Practice at the recognition needed to classify natural products.

Suggested solution
Grandisol and polyzonimine have ten carbon atoms each with branched chains having methyl groups at the branchpoints. They are terpenes and specifically monoterpenes. You might also have said that polyzonimine is an alkaloid as it has a basic nitrogen. Serotonin is an amino acid metabolite derived from tryptophan. Scytalone has the characteristic unbranched chain and alternate oxygen atoms of a polyketide, an aromatic pentaketide in fact. Pelletierine is an alkaloid, specifically a piperidine alkaloid.

They are also an insect pheromone (grandisol), a defence substance (polyzonimine), an important human metabolite (serotonin), a fungal metabolite (scytalone), and a toxic compound from hemlock (pelletierine).
PROBLEM 10
The piperidine alkaloid pelletierine, mentioned in problem 9, is made in nature from the amino acid lysine by pyridoxal chemistry. Fill in the details from this outline:

H₂N  \[ \rightarrow \]  CO₂H  \[ \rightarrow \]  NH₂  \[ \rightarrow \]  lysine

\[
\text{RNH}_2 \text{ is pyridoxamine}
\]

\[
\text{CoAS} \rightarrow \text{N} \quad \text{H}  \quad \text{NHR}  \quad \text{H}  \quad \text{Enz}
\]

\[
\text{HN}  \quad \text{NH}  \quad \text{CO₂H}  \quad \text{HN}  \quad \text{NH}  \quad \text{pelletierine}
\]

Purpose of the problem
A more thorough exploration of the biosynthesis of one group of alkaloids.

Suggested solution
The first stage produces the usual pyridoxal imine/enamine compound and decarboxylation gives a compound that can cyclize and give the cyclic iminium salt by loss of pyridoxamine.

\[
\text{H₂N} \quad \text{CO₂H} \quad \text{RCHO} \quad \text{pyridoxal} \quad \text{RNH}_2 \quad \text{is pyridoxamine}
\]

\[
\text{H₂N} \quad \text{CO₂H} \quad \text{HN} \quad \text{NH} \quad \text{R} \quad \text{HN} \quad \text{RNH}_2 \quad \text{Enz}
\]

Now the enol of acetyl CoA adds to the iminium salt to complete the skeleton of the piperidine alkaloids. Hydrolysis and decarboxylation gives pelletierine.
PROBLEM 11

Aromatic polyketides are typically biosynthesized from linear ketoacids with a carboxylic acid terminus. Suggest what polyketide starting material might be the precursor of orsellinic acid and how the cyclization might occur.

Purpose of the problem

More detail on polyketide folding.

Suggested solution

Looking at this problem as if it were a chemical synthesis, we could disconnect orsellinic acid by aldol style chemistry.

But how are we to go further? Those cis alkenes and alcohols are a problem. This is easily resolved as the alkenes are enols and we need to replace them by the corresponding ketones.

We discover a linear polyketide derived from an acetate starter and three malonyl CoA units. The only C–C bond that needs to be made is the one

See p. 1162 of the textbook.
that closes the six-membered ring. Enolization then gives aromatic orsellinic acid.

**PROBLEM 12**

Chemists like to make model compounds to see whether their ideas about mechanisms in nature can be reproduced in simple organic compounds. Nature’s reducing agent is NADPH and, unlike NaBH₄, it reduces stereospecifically (p. 1150 of the textbook). A model for a proposed mechanism uses a much simpler molecule with a close resemblance to NADH. Acylation and treatment with Mg(II) causes stereospecific reduction of the remote ketone. Suggest a mechanism for this stereochemical control. How would you release the reduced product?

![Chemical reactions and structures](image)

**Purpose of the problem**

An example of a model compound to support mechanistic suggestions.

**Suggested solution**

The ketone is too far away from the chiral centre for there to be any interaction across space. The idea was that the side chain would bend backwards so that the benzene ring would sit on top of the pyridine ring and that this could happen with NADH too.
This is a difficult problem but examination of the proposed mechanism should show you that binding to the magnesium holds the side chain over the pyridine ring. Enzymatic reactions often use binding to metals to hold substrates in position. Of course, in this example, the substrate is covalently bound to the reagent but simple ester exchange with MeO⁻ in MeOH releases it.

**PROBLEM 13**

Both humulene, a flavouring substance in beer, and caryophylene, a component of the flavour of cloves, are made in nature from farnesyl pyrophosphate. Suggest detailed pathways. How do the enzymes control which product will be formed?

---

**Purpose of the problem**

Some serious terpene biosynthesis for you to unravel.

**Suggested solution**

Judging from the number of carbon atoms (15) and the pattern of their methyl groups, these closely related compounds are clearly sequiterpenes. They can both be derived from the same intermediate by cyclization of farnesyl pyrophosphate without the need to isomerize an alkene. The eleven-membered ring in humulene can accommodate three E-alkenes.

Caryophyllene needs a second cyclization to give a four-membered ring—the stereochemistry is already there in the way that the molecule folds—and a proton must be lost. The enzymes control the processes so that the starting material is held in the right shape and, more subtly, to make the ‘wrong’
(more substituted) end of the alkene cyclize in the humulene synthesis. It might do this by removing the proton as the cyclization happens.

PROBLEM 14
This experiment aims to imitate the biosynthesis of terpenes. A mixture of products results. Draw a mechanism for the reaction. To what extent is it biomimetic, and what can the natural system do better?

Purpose of the problem
Reminder of the weaknesses inherent in, and the reassurance possible from, biomimetic experiments.

Suggested solution
The relatively weak leaving group (acetate) is lost from the allylic acetate with Lewis acid catalysis to give a stable allyl cation. This couples with the other (isopentenyl) acetate in a way very similar to the natural process. However, what happens to the resulting cation is not well controlled. Loss of each of the three marked protons gives a different product. In the enzymatic reaction, loss of the proton would probably be concerted with C–C bond formation as a basic group, such as an imidazole of histidine or a carboxylate anion, would be in the right position to remove one of the protons selectively.

These experiments still give us confidence that the rather remarkable reactions proposed for the biosynthesis are feasible: M. Julia et al., J. Chem. Res., 1978, 268, 269
The second edition of the Solutions manual to accompany Organic Chemistry provides detailed worked solutions to all of the problems that have been written to accompany Organic Chemistry, second edition, by Clayden, Greeves, and Warren. The problems themselves may be found online at www.oxfordtextbooks.co.uk/orc/clayden2e/

The purpose behind each problem is briefly discussed, and a suggested solution is presented. As in the parent textbook, the emphasis is on understanding rather than factual knowledge alone, and the authors provide friendly guidance in the explanation of each solution. Helpful notes in the margin highlight important principles, make general comments, or direct the reader to further information in the chemical literature.
Clayden, Greeves, Warren and Wothers

ORGANIC CHEMISTRY
## Table of Contents

What is organic chemistry?

Organic chemistry and you

You are already a highly skilled organic chemist. As you read these words, your eyes are using an organic compound (retinal) to convert visible light into nerve impulses. When you picked up this book, your muscles were doing chemical reactions on sugars to give you the energy you needed. As you understand, gaps between your brain cells are being bridged by simple organic molecules (neurotransmitter amines) so that nerve impulses can be passed around your brain. And you did all that without consciously thinking about it. You do not yet understand these processes in your mind as well as you can carry them out in your brain and body. You are not alone there. No organic chemist, however brilliant, understands the detailed chemical working of the human mind or body very well.

We, the authors, include ourselves in this generalization, but we are going to show you in this book what enormous strides have been taken in the understanding of organic chemistry since the science came into being in the early years of the nineteenth century. Organic chemistry began as a tentative attempt to understand the chemistry of life. It has grown into the confident basis of vast multinational industries that feed, clothe, and cure millions of people without their even being aware of the role of chemistry in their lives. Chemists cooperate with physicists and mathematicians to understand how molecules behave and with biologists to understand how molecules determine life processes. The development of these ideas is already a revelation at the beginning of the twenty-first century, but is far from complete. We aim not to give you the measurements of the skeleton of a dead science but to equip you to understand the conflicting demands of an adolescent one.

Like all sciences, chemistry has a unique place in our pattern of understanding of the universe. It is the science of molecules. But organic chemistry is something more. It literally creates itself as it grows. Of course we need to study the molecules of nature both because they are interesting in their own right and because their functions are important to our lives. Organic chemistry often studies life by making new molecules that give information not available from the molecules actually present in living things.

This creation of new molecules has given us new materials such as plastics, new dyes to colour our clothes, new perfumes to wear, new drugs to cure diseases. Some people think that these activities are unnatural and their products dangerous or unwholesome. But these new molecules are built by humans from other molecules found on earth using the skills inherent in our natural brains. Birds build nests; man makes houses. Which is unnatural? To the organic chemist this is a meaningless distinction. There are toxic compounds and nutritious ones, stable compounds and reactive ones—but there is only one type of chemistry: it goes on both inside our brains and bodies and also in our flasks and reactors, born from the ideas in our minds and the skill in our hands. We are not going to set ourselves up as moral judges in any way. We believe it is right to try and understand the world about us as best we can and to use that understanding creatively. This is what we want to share with you.

Organic compounds

Organic chemistry started as the chemistry of life, when that was thought to be different from the chemistry in the laboratory. Then it became the chemistry of carbon compounds, especially those found in coal. Now it is both. It is the chemistry of the compounds of carbon along with other elements such as are found in living things and elsewhere.
The organic compounds available to us today are those present in living things and those formed over millions of years from dead things. In earlier times, the organic compounds known from nature were those in the ‘essential oils’ that could be distilled from plants and the alkaloids that could be extracted from crushed plants with acid. Menthol is a famous example of a flavouring compound from the essential oil of spearmint and cis-jasmon an example of a perfume distilled from jasmine flowers.

Even in the sixteenth century one alkaloid was famous—quinine was extracted from the bark of the South American cinchona tree and used to treat fevers, especially malaria. The Jesuits who did this work (the remedy was known as ‘Jesuit’s bark’) did not of course know what the structure of quinine was, but now we do.

The main reservoir of chemicals available to the nineteenth century chemists was coal. Distillation of coal to give gas for lighting and heating (mainly hydrogen and carbon monoxide) also gave a brown tar rich in aromatic compounds such as benzene, pyridine, phenol, aniline, and thiophene.

Phenol was used by Lister as an antiseptic in surgery and aniline became the basis for the dyestuffs industry. It was this that really started the search for new organic compounds made by chemists rather than by nature. A dyestuff of this kind—still available—is Bismarck Brown, which should tell you that much of this early work was done in Germany.

In the twentieth century oil overtook coal as the main source of bulk organic compounds so that simple hydrocarbons like methane (CH₄, ‘natural gas’) and propane (CH₃CH₂CH₃, ‘calor gas’) became available for fuel. At the same time chemists began the search for new molecules from new sources such as fungi, corals, and bacteria and two organic chemical industries developed in parallel—‘bulk’ and ‘fine’ chemicals. Bulk chemicals like paints and plastics are usually based on simple molecules produced in multiton quantities while fine chemicals such as drugs, perfumes, and flavouring materials are produced in smaller quantities but much more profitably.

At the time of writing there were about 16 million organic compounds known. How many more are possible? There is no limit (except the number of atoms in the universe). Imagine you’ve just made the longest hydrocarbon ever made—you just have to add another carbon atom and you’ve made another. This process can go on with any type of compound ad infinitum.

But these millions of compounds are not just a long list of linear hydrocarbons; they embrace all kinds of molecules with amazingly varied properties. In this chapter we offer a selection.
What do they look like? They may be crystalline solids, oils, waxes, plastics, elastics, mobile or volatile liquids, or gases. Familiar ones include white crystalline sugar, a cheap natural compound isolated from plants as hard white crystals when pure, and petrol, a mixture of colourless, volatile, flammable hydrocarbons. Isooctane is a typical example and gives its name to the octane rating of petrol.

The compounds need not lack colour. Indeed we can soon dream up a rainbow of organic compounds covering the whole spectrum, not to mention black and brown. In this table we have avoided dyestuffs and have chosen compounds as varied in structure as possible.

Colour is not the only characteristic by which we recognize compounds. All too often it is their odour that lets us know they are around. There are some quite foul organic compounds too; the smell of the skunk is a mixture of two thiols—sulfur compounds containing SH groups.

skunk spray contains:

- ![Structure](structure7.png) + ![Structure](structure8.png)
But perhaps the worst aroma was that which caused the evacuation of the city of Freiburg in 1889. Attempts to make thioacetone by the cracking of trithioacetone gave rise to ‘an offensive smell which spread rapidly over a great area of the town causing fainting, vomiting and a panic evacuation—the laboratory work was abandoned’.

It was perhaps foolhardy for workers at an Esso research station to repeat the experiment of cracking trithioacetone south of Oxford in 1967. Let them take up the story. ‘Recently we found ourselves with an odour problem beyond our worst expectations. During early experiments, a stopper jumped from a bottle of residues, and, although replaced at once, resulted in an immediate complaint of nausea and sickness from colleagues working in a building two hundred yards away. Two of our chemists who had done no more than investigate the cracking of minute amounts of trithioacetone found themselves the object of hostile stares in a restaurant and suffered the humiliation of having a waitress spray the area around them with a deodorant. The odours defied the expected effects of dilution since workers in the laboratory did not find the odours intolerable . . . and genuinely denied responsibility since they were working in closed systems. To convince them otherwise, they were dispersed with other observers around the laboratory, at distances up to a quarter of a mile, and one drop of either acetone gem-dithiol or the mother liquors from crude trithioacetone crystallisations were placed on a watch glass in a fume cupboard. The odour was detected downwind in seconds.’

There are two candidates for this dreadful smell—propane dithiol (called acetone gem-dithiol above) or 4-methyl-4-sulfanylpentan-2-one. It is unlikely that anyone else will be brave enough to resolve the controversy.

Nasty smells have their uses. The natural gas piped to our homes contains small amounts of deliberately added sulfur compounds such as tert-butyl thiol \((\text{CH}_3)_3\text{CSH}\). When we say small, we mean very small—humans can detect one part in 50,000,000,000 parts of natural gas.

Other compounds have delightful odours. To redeem the honour of sulfur compounds we must cite the truffle which pigs can smell through a metre of soil and whose taste and smell is so delightful that truffles cost more than their weight in gold. Damascenones are responsible for the smell of roses. If you smell one drop you will be disappointed, as it smells rather like turpentine or camphor, but next morning you and the clothes you were wearing will smell powerfully of roses. Just like the compounds from trithioacetone, this smell develops on dilution.

Humans are not the only creatures with a sense of smell. We can find mates using our eyes alone (though smell does play a part) but insects cannot do this. They are small in a crowded world and they find others of their own species and the opposite sex by smell. Most insects produce volatile compounds that can be picked up by a potential mate in incredibly weak concentrations. Only 1.5 mg of serricornin, the sex pheromone of the cigarette beetle, could be isolated from 65,000 female beetles—so there isn’t much in each beetle. Nevertheless, the slightest whiff of it causes the males to gather and attempt frenzied copulation.

The sex pheromone of the Japanese beetle, also given off by the females, has been made by chemists. As little as 5 \(\mu\)g (micrograms, note!) was more effective than four virgin females in attracting the males.

The pheromone of the gypsy moth, disparlure, was identified from a few \(\mu\)g isolated from the moths and only 10 \(\mu\)g of synthetic material. As little as \(2 \times 10^{-12}\) g is active as a lure for the males in field tests. The three pheromones we have mentioned are available commercially for the specific trapping of these destructive insect pests.
Don’t suppose that the females always do all the work; both male and female olive flies produce pheromones that attract the other sex. The remarkable thing is that one mirror image of the molecule attracts the males while the other attracts the females!

What about taste? Take the grapefruit. The main flavour comes from another sulfur compound and human beings can detect $2 \times 10^{-5}$ parts per billion of this compound. This is an almost unimaginably small amount equal to $10^{-4}$ mg per tonne or a drop, not in a bucket, but in a good-sized lake. Why evolution should have left us abnormally sensitive to grapefruit, we leave you to imagine.

For a nasty taste, we should mention ‘bittering agents’, put into dangerous household substances like toilet cleaner to stop children eating them by accident. Notice that this complex organic compound is actually a salt—it has positively charged nitrogen and negatively charged oxygen atoms—and this makes it soluble in water.

Other organic compounds have strange effects on humans. Various ‘drugs’ such as alcohol and cocaine are taken in various ways to make people temporarily happy. They have their dangers. Too much alcohol leads to a lot of misery and any cocaine at all may make you a slave for life.

Again, let’s not forget other creatures. Cats seem to be able to go to sleep at any time and recently a compound was isolated from the cerebrospinal fluid of cats that makes them, or rats, or humans go off to sleep quickly. It is a surprisingly simple compound.

This compound and disparlure are both derivatives of fatty acids, molecules that feature in many of the food problems people are so interested in now (and rightly so). Fatty acids in the diet are a popular preoccupation and the good and bad qualities of saturates, monounsaturates, and polyunsaturates are continually in the news. This too is organic chemistry. One of the latest molecules to be recognized as an anticancer agent in our diet is CLA (conjugated linoleic acid) in dairy products.
Another fashionable molecule is resveratrole, which may be responsible for the beneficial effects of red wine in preventing heart disease. It is a quite different organic compound with two benzene rings and you can read about it in Chapter 51.

For our third edible molecule we choose vitamin C. This is an essential factor in our diets—indeed, that is why it is called a vitamin. The disease scurvy, a degeneration of soft tissues, particularly in the mouth, from which sailors on long voyages like those of Columbus suffered, results if we don’t have vitamin C. It also is a universal antioxidant, scavenging for rogue free radicals and so protecting us against cancer. Some people think an extra large intake protects us against the common cold, but this is not yet proved.

**Organic chemistry and industry**

Vitamin C is manufactured on a huge scale by Roche, a Swiss company. All over the world there are chemistry-based companies making organic molecules on scales varying from a few kilograms to thousands of tonnes per year. This is good news for students of organic chemistry; there are lots of jobs around and it is an international job market. The scale of some of these operations of organic chemistry is almost incredible. The petrochemicals industry processes (and we use the products!) over 10 million litres of crude oil every day. Much of this is just burnt in vehicles as petrol or diesel, but some of it is purified or converted into organic compounds for use in the rest of the chemical industry. Multinational companies with thousands of employees such as Esso (Exxon) and Shell dominate this sector.

Some simple compounds are made both from oil and from plants. The ethanol used as a starting material to make other compounds in industry is largely made by the catalytic hydration of ethylene from oil. But ethanol is also used as a fuel, particularly in Brazil where it is made by fermentation of sugar cane wastes. This fuel uses a waste product, saves on oil imports, and has improved the quality of the air in the very large Brazilian cities, Rio de Janeiro and São Paulo.

Plastics and polymers take much of the production of the petrochemical industry in the form of monomers such as styrene, acrylates, and vinyl chloride. The products of this enormous industry are everything made of plastic including solid plastics for household goods and furniture, fibres for clothes (24 million tonnes per annum), elastic polymers for car tyres, light bubble-filled polymers for packing, and so on. Companies such as BASF, Dupont, Amoco, Monsanto, Laporte, Hoechst, and ICI are leaders here. Worldwide polymer production approaches 100 million tonnes per annum and PVC manufacture alone employs over 50 000 people to make over 20 million tonnes per annum.

The washing-up bowl is plastic too but the detergent you put in it belongs to another branch of the chemical industry—companies like Unilever (Britain) or Procter and Gamble (USA) which produce soap, detergent, cleaners, bleaches, polishes, and all the many essentials for the modern home. These products may be lemon and lavender scented but they too mostly come from the oil industry. Nowadays, most products of this kind tell us, after a fashion, what is in them. Try this example—a well known brand of shaving gel along with the list of contents on the container:

<table>

The structures of two dyes

Fast Green FCF and Quinoline Yellow are colours permitted to be used in foods and cosmetics and have the structures shown here. Quinoline Yellow is a mixture of isomeric sulfonic acids in the two rings shown.

The particular acids, bases, surfactants, and so on are chosen to blend together in a smooth emulsion when propelled from the can. The result should feel, smell, and look attractive and a greenish colour is considered clean and antiseptic by the customer. What the can actually says is this: ‘Superior lubricants within the gel prepare the skin for an exceptionally close, comfortable and effective shave. It contains added moisturisers to help protect the skin from razor burn. Lightly fragranced.’
Another oil-derived class of organic chemical business includes adhesives, sealants, coatings, and so on, with companies like Ciba–Geigy, Dow, Monsanto, and Laporte in the lead. Nowadays aircraft are glued together with epoxy-resins and you can glue almost anything with ‘Superglue’ a polymer of methyl cyanoacrylate.

There is a big market for intense colours for dyeing cloth, colouring plastic and paper, painting walls, and so on. This is the dyestuffs and pigments industry and leaders here are companies like ICI and Akzo Nobel. ICI have a large stake in this aspect of the business, their paints turnover alone being £2 003 000 000 in 1995.

The most famous dyestuff is probably indigo, an ancient dye that used to be isolated from plants but is now made chemically. It is the colour of blue jeans. More modern dyestuffs can be represented by ICI’s benzodifuranones, which give fashionable red colours to synthetic fabrics like polyesters.

We see one type of pigment around us all the time in the form of the colours on plastic bags. Among the best compounds for these are the metal complexes called phthalocyanines. Changing the metal (Cu and Fe are popular) at the centre and the halogens round the edge of these molecules changes the colour but blues and green predominate. The metal atom is not necessary for intense pigment colours—one new class of intense ‘high performance’ pigments in the orange–red range are the DPP (1,4-diketopyrrolo[3,4-c]pyrroles) series developed by Ciba–Geigy. Pigment Red 254 is used in paints and plastics.

Colour photography starts with inorganic silver halides but they are carried on organic gelatin. Light acts on silver halides to give silver atoms that form the photographic image, but only in black and white. The colour in films like Kodachrome then comes from the coupling of two colourless organic compounds. One, usually an aromatic amine, is oxidized and couples with the other to give a coloured compound.
That brings us to flavours and fragrances. Companies like International Flavours and Fragrances (USA) or Givaudan–Roure (Swiss) produce very big ranges of fine chemicals for the perfume, cosmetic, and food industries. Many of these will come from oil but others come from plant sources. A typical perfume will contain 5–10% fragrances in an ethanol/water (about 90:10) mixture. So the perfumery industry needs a very large amount of ethanol and, you might think, not much perfumery material. In fact, important fragrances like jasmine are produced on a >10 000 tonnes per annum scale. The cost of a pure perfume ingredient like cis-jasmone, the main ingredient of jasmine, may be several hundred pounds, dollars, or euros per gram.

The world of perfumery

Perfume chemists use extraordinary language to describe their achievements: ‘Paco Rabanne pour homme was created to reproduce the effect of a summer walk in the open air among the hills of Provence: the smell of herbs, rosemary and thyme, and sparkling freshness with cool sea breezes mingling with warm soft Alpine air. To achieve the required effect, the perfumer blended herbaceous oils with woody accords and the synthetic aroma chemical dimethylheptanol which has a penetrating but indefinable freshness associated with open air or freshly washed linen’. (J. Ayres, Chemistry and Industry, 1988, 579)

Chemists produce synthetic flavourings such as ‘smoky bacon’ and even ‘chocolate’. Meaty flavours come from simple heterocycles such as alkyl pyrazines (present in coffee as well as roast meat) and furonol, originally found in pineapples. Compounds such as corylone and maltol give caramel and meaty flavours. Mixtures of these and other synthetic compounds can be ‘tuned’ to taste like many roasted foods from fresh bread to coffee and barbecued meat.

Some flavouring compounds are also perfumes and may also be used as an intermediate in making other compounds. Two such large-scale flavouring compounds are vanillin (vanilla flavour as in ice cream) and menthol (mint flavour) both manufactured on a large scale and with many uses.

Food chemistry includes much larger-scale items than flavourings. Sweeteners such as sugar itself are isolated from plants on an enormous scale. Sugar’s structure appeared a few pages back. Other sweeteners such as saccharin (discovered in 1879!) and aspartame (1965) are made on a sizeable scale. Aspartame is a compound of two of the natural amino acids present in all living things and is made by Monsanto on a large scale (over 10 000 tonnes per annum).
The pharmaceutical businesses produce drugs and medicinal products of many kinds. One of the great revolutions of modern life has been the expectation that humans will survive diseases because of a treatment designed to deal specifically with that disease. The most successful drug ever is ranitidine (Zantac), the Glaxo–Wellcome ulcer treatment, and one of the fastest-growing is Pfizer’s sildenafil (Viagra). ‘Success’ refers both to human health and to profit!

You will know people (probably older men) who are ‘on β-blockers’. These are compounds designed to block the effects of adrenaline (epinephrine) on the heart and hence to prevent heart disease. One of the best is Zeneca’s tenormin. Preventing high blood pressure also prevents heart disease and certain specific enzyme inhibitors (called ‘ACE-inhibitors’) such as Squibb’s captopril work in this way. These are drugs that imitate substances naturally present in the body.

The treatment of infectious diseases relies on antibiotics such as the penicillins to prevent bacteria from multiplying. One of the most successful of these is Smith Kline Beecham’s amoxicillin. The four-membered ring at the heart of the molecule is the ‘β-lactam’.

We cannot maintain our present high density of population in the developed world, nor deal with malnutrition in the developing world unless we preserve our food supply from attacks by insects and fungi and from competition by weeds. The world market for agrochemicals is over £10 000 000 000 per annum divided roughly equally between herbicides, fungicides, and insecticides.

At the moment we hold our own by the use of agrochemicals: companies such as Rhône-Poulenc, Zeneca, BASF, Schering–Plough, and Dow produce compounds of remarkable and specific activity. The most famous modern insecticides are modelled on the natural pyrethrins, stabilized against degradation by sunlight by chemical modification (see coloured portions of decamethrin) and targeted to specific insects on specific crops in cooperation with biologists. Decamethrin has a safety factor of >10^6 for mustard beetles over mammals, can be applied at only 10 grams per hectare (about one level tablespoon per football pitch), and leaves no significant environmental residue.
As you learn more chemistry, you will appreciate how remarkable it is that Nature should produce three-membered rings and that chemists should use them in bulk compounds to be sprayed on crops in fields. Even more remarkable in some ways is the new generation of fungicides based on a five-membered ring containing three nitrogen atoms—the triazole ring. These compounds inhibit an enzyme present in fungi but not in plants or animals.

One fungus (potato blight) caused the Irish potato famine of the nineteenth century and the various blights, blotches, rots, rusts, smuts, and mildews can overwhelm any crop in a short time. Especially now that so much is grown in Western Europe in winter, fungal diseases are a real threat.

Organic chemistry and the periodic table

All the compounds we have shown you are built up on hydrocarbon (carbon and hydrogen) skeletons. Most have oxygen and/or nitrogen as well; some have sulfur and some phosphorus. These are the main elements of organic chemistry but another way the science has developed is an exploration of (some would say take-over bid for) the rest of the periodic table. Some of our compounds also had fluorine, sodium, copper, chlorine, and bromine. The organic chemistry of silicon, boron, lithium, the halogens (F, Cl, Br, and I), tin, copper, and palladium has been particularly well studied and these elements commonly form part of organic reagents used in the laboratory. They will crop up throughout this book. These ‘lesser’ elements appear in many important reagents, which are used in organic chemical laboratories all over the world. Butyllithium, trimethylsilyl chloride, tributyltin hydride, and dimethylcopper lithium are good examples.

The halogens also appear in many life-saving drugs. The recently discovered antiviral compounds, such as fialuridine (which contains both F and I, as well as N and O), are essential for the fight against HIV and AIDS. They are modelled on natural compounds from nucleic acids. The naturally occurring cytotoxic (antitumour) agent halomon, extracted from red algae, contains Br and Cl.

Another definition of organic chemistry would use the periodic table. The key elements in organic chemistry are of course C, H, N, and O, but also important are the halogens (F, Cl, Br, I),
p-block elements such as Si, S, and P, metals such as Li, Pd, Cu, and Hg, and many more. We can construct an organic chemist’s periodic table with the most important elements emphasized:

So where does inorganic chemistry end and organic chemistry begin? Would you say that the antiviral compound foscarnet was organic? It is a compound of carbon with the formula $\text{CPO}_5\text{Na}_3$, but it has no C–H bonds. And what about the important reagent tetrakis triphenyl phosphine palladium? It has lots of hydrocarbon—twelve benzene rings in fact—but the benzene rings are all joined to phosphorus atoms that are arranged in a square around the central palladium atom, so the molecule is held together by C–P and P–Pd bonds, not by a hydrocarbon skeleton. Although it has the very organic-looking formula $\text{C}_{72}\text{H}_{60}\text{P}_4\text{Pd}$, many people would say it is inorganic. But is it?

The answer is that we don’t know and we don’t care. It is important these days to realize that strict boundaries between traditional disciplines are undesirable and meaningless. Chemistry continues across the old boundaries between organic chemistry and inorganic chemistry on the one side and organic chemistry and biochemistry on the other. Be glad that the boundaries are indistinct as that means the chemistry is all the richer. This lovely molecule $(\text{Ph}_3\text{P})_4\text{Pd}$ belongs to chemistry.
We have told you about organic chemistry's history, the types of compounds it concerns itself with, the things it makes, and the elements it uses. Organic chemistry today is the study of the structure and reactions of compounds in nature of compounds, in the fossil reserves such as coal and oil, and of those compounds that can be made from them. These compounds will usually be constructed with a hydrocarbon framework but will also often have atoms such as O, N, S, P, Si, B, halogens, and metals attached to them. Organic chemistry is used in the making of plastics, paints, dyestuffs, clothes, foodstuffs, human and veterinary medicines, agrochemicals, and many other things. Now we can summarize all of these in a different way.

This book is about all these things. It tells you about the structures of organic molecules and the reasons behind them. It tells you about the shapes of those molecules and how the shape relates to their function, especially in the context of biology. It tells you how those structures and shapes are discovered. It tells you about the reactions the molecules undergo and, more importantly, how and why they behave in the way they do. It tells you about nature and about industry. It tells you how molecules are made and how you too can think about making molecules.

We said 'it tells' in that last paragraph. Maybe we should have said 'we tell' because we want to speak to you through our words so that you can see how we think about organic chemistry and to encourage you to develop your own ideas. We expect you to notice that four people have written this book and that they don’t all think or write in the same way. That is as it should be. Organic chemistry is too big and important a subject to be restricted by dogmatic rules. Different chemists think in different ways about many aspects of organic chemistry and in many cases it is not yet possible to be sure who is right.

We may refer to the history of chemistry from time to time but we are usually going to tell you about organic chemistry as it is now. We will develop the ideas slowly, from simple and fundamental ones using small molecules to complex ideas and large molecules. We promise one thing. We are not going to pull the wool over your eyes by making things artificially simple and avoiding the awkward questions. We aim to be honest and share both our delight in good complete explanations and our puzzlement at inadequate ones. So how are we going to do this? The book starts with a series of chapters on the structures and reactions of simple molecules. You will meet the way structures are determined and the theory that explains those structures. It is vital that you realize that theory is used to explain what is known by experiment and only then to predict what is unknown. You will meet mechanisms—the dynamic language used by chemists to talk about reactions—and of course some reactions.
The book starts with an introductory section of four chapters:

1. What is organic chemistry?
2. Organic structures
3. Determining organic structures
4. Structure of molecules

In Chapter 2 you will look at the way in which we are going to present diagrams of molecules on the printed page. Organic chemistry is a visual, three-dimensional subject and the way you draw molecules shows how you think about them. We want you too to draw molecules in the best way available now. It is just as easy to draw them well as to draw them in an old-fashioned inaccurate way.

Then in Chapter 3, before we come to the theory of molecular structure, we shall introduce you to the experimental techniques of finding out about molecular structure. This means studying the interactions between molecules and radiation by spectroscopy—using the whole electromagnetic spectrum from X-rays to radio waves. Only then, in Chapter 4, will we go behind the scenes and look at the theories of why atoms combine in the ways they do. Experiment comes before theory. The spectroscopic methods of Chapter 3 will still be telling the truth in a hundred years time, but the theories of Chapter 4 will look quite dated by then.

We could have titled those three chapters:

2. What shapes do organic molecules have?
3. How do we know they have those shapes?
4. Why do they have those shapes?

You need to have a grasp of the answers to these three questions before you start the study of organic reactions. That is exactly what happens next. We introduce organic reaction mechanisms in Chapter 5. Any kind of chemistry studies reactions—the transformations of molecules into other molecules. The dynamic process by which this happens is called mechanism and is the language of organic chemistry. We want you to start learning and using this language straight away so in Chapter 6 we apply it to one important class of reaction. This section is:

5. Organic reactions

6. Nucleophilic addition to the carbonyl group

Chapter 6 reveals how we are going to subdivide organic chemistry. We shall use a mechanistic classification rather than a structural classification and explain one type of reaction rather than one type of compound in each chapter. In the rest of the book most of the chapters describe types of reaction in a mechanistic way. Here is a selection.

7. Using organometallic reagents to make C–C bonds

8. Nucleophilic substitution at saturated carbon

9. Electrophilic addition to alkenes

10. Electrophilic aromatic substitution

11. Conjugate Michael addition of enolates

12. Radicals

Interspersed with these chapters are others on physical aspects, organic synthesis, stereochemistry, structural determination, and biological chemistry as all these topics are important parts of organic chemistry.

‘Connections’ section

Chemistry is not a linear subject! It is impossible simply to start at the beginning and work through to the end, introducing one new topic at a time, because chemistry is a network of interconnecting ideas. But, unfortunately, a book is, by nature, a beginning-to-end sort of thing. We have arranged the chapters in a progression of difficulty as far as is possible, but to help you find your way around
we have included at the beginning of each chapter a ‘Connections’ section. This tells you three things divided among three columns:

(a) what you should be familiar with before reading the chapter—in other words, which previous chapters relate directly to the material within the chapter ('Building on' column)

(b) a guide to what you will find within the chapter ('Arriving at' column)

(c) which chapters later in the book fill out and expand the material in the chapter ('Looking forward to' column)

The first time you read a chapter, you should really make sure you have read any chapter mentioned under (a). When you become more familiar with the book you will find that the links highlighted in (a) and (c) will help you see how chemistry interconnects with itself.

Boxes and margin notes

The other things you should look out for are the margin notes and boxes. There are four sorts, and they have all appeared at least once in this chapter.

End-of-chapter problems

You can’t learn organic chemistry—there’s just too much of it. You can learn trivial things like the names of compounds but that doesn’t help you understand the principles behind the subject. You have to understand the principles because the only way to tackle organic chemistry is to learn to work it out. That is why we have provided end-of-chapter problems. They are to help you discover if you have understood the material presented in each chapter. In general, the 10–15 problems at the end of each chapter start easy and get more difficult. They come in two sorts. The first, generally shorter and easier, allow you to revise the material in that chapter. The second asks you to extend your understanding of the material into areas not covered by the chapter. In the later chapters this second sort will probably revise material from previous chapters.

If a chapter is about a certain type of organic reaction, say elimination reactions (Chapter 19), the chapter itself will describe the various ways (‘mechanisms’) by which the reaction can occur and it will give definitive examples of each mechanism. In Chapter 19 there are three mechanisms and about 65 examples altogether. You might think that this is rather a lot but there are in fact millions of examples known of these three mechanisms and Chapter 19 only scarpes the surface. Even if you totally comprehended the chapter at a first reading, you could not be confident of your understanding about elimination reactions. There are 13 end-of-chapter problems for Chapter 19. The first three ask you to interpret reactions given but not explained in the chapter. This checks that you can use the ideas in familiar situations. The next few problems develop specific ideas from the chapter concerned with why one compound does one reaction while a similar one behaves quite differently.
Finally there are some more challenging problems asking you to extend the ideas to unfamiliar molecules.

The end-of-chapter problems should set you on your way but they are not the end of the journey to understanding. You are probably reading this text as part of a university course and you should find out what kind of examination problems your university uses and practise them too. Your tutor will be able to advise you on suitable problems for each stage of your development.

**The solutions manual**

The problems would be of little use to you if you could not check your answers. For the maximum benefit, you need to tackle some or all of the problems as soon as you have finished each chapter without looking at the answers. Then you need to compare your suggestions with ours. You can do this with the solutions manual (*Organic Chemistry: Solutions Manual*, Oxford University Press, 2000). Each problem is discussed in some detail. The purpose of the problem is first stated or explained. Then, if the problem is a simple one, the answer is given. If the problem is more complex, a discussion of possible answers follows with some comments on the value of each. There may be a reference to the source of the problem so that you can read further if you wish.

**Colour**

You will already have noticed something unusual about this book: almost all of the chemical structures are shown in red. This is quite intentional: emphatic red underlines the message that structures are more important than words in organic chemistry. But sometimes small parts of structures are in other colours: here are two examples from p. 000, where we were talking about organic compounds containing elements other than C and H.

Why are the atom labels black? Because we wanted them to stand out from the rest of the molecule. In general you will see black used to highlight important details of a molecule—they may be the groups taking part in a reaction, or something that has changed as a result of the reaction, as in these examples from Chapters 9 and 12.

We shall often use black to emphasize ‘curly arrows’, devices that show the movement of electrons, and whose use you will learn about in Chapter 5. Here is an example from Chapter 10: notice black also helps the ‘+’ and ‘−’ charges to stand out.
Occasionally, we shall use other colours such as green, or even orange, yellow, or brown, to highlight points of secondary importance. This example is part of a reaction taken from Chapter 19: we want to show that a molecule of water ($H_2O$) is formed. The green atoms show where the water comes from. Notice black curly arrows and a new black bond.

Other colours come in when things get more complicated—in this Chapter 24 example, we want to show a reaction happening at the black group in the presence of the yellow H (which, as you will see in Chapter 9, also reacts) and also in the presence of the green ‘protecting’ groups, one of the topics of Chapter 24.

And, in Chapter 16, colour helps us highlight the difference between carbon atoms carrying four different groups and those with only three different groups. The message is: if you see something in a colour other than red, take special note—the colour is there for a reason.

That is all we shall say in the way of introduction. On the next page the real chemistry starts, and our intention is to help you to learn real chemistry, and to enjoy it.
There are over 100 elements in the periodic table. Many molecules contain well over 100 atoms—palytoxin, for example (a naturally occurring compound with potential anticancer activity) contains 129 carbon atoms, 221 hydrogen atoms, 54 oxygen atoms, and 3 nitrogen atoms. It’s easy to see how chemical structures can display enormous variety, providing enough molecules to build even the most complicated living creatures. But how can we understand what seems like a recipe for confusion? Faced with the collection of atoms we call a molecule, how can we make sense of what we see? This chapter will teach you how to interpret organic structures. It will also teach you how to draw organic molecules in a way that conveys all the necessary information and none of the superfluous.

Palytoxin was isolated in 1971 in Hawaii from *Limu make o Hana* (‘deadly seaweed of Hana’) which had been used to poison spear points. It is one of the most toxic compounds known requiring only about 0.15 microgram per kilogram for death by injection. The complicated structure was determined a few years later.

Hydrocarbon frameworks and functional groups

As we explained in Chapter 1, organic chemistry is the study of compounds that contain carbon. Nearly all organic compounds also contain hydrogen; most also contain oxygen, nitrogen, or other elements. Organic chemistry concerns itself with the way in which these atoms are bonded together into stable molecular structures, and the way in which these structures change in the course of chemical reactions.

Some molecular structures are shown below. These molecules are all amino acids, the constituents of proteins. Look at the number of carbon atoms in each molecule and the way they are bonded together. Even within this small class of molecules there’s great variety—glycine and alanine have only two or three carbon atoms; phenylalanine has nine. Lysine has a chain of atoms; tryptophan has rings.

In methionine the atoms are arranged in a single chain; in leucine the chain is branched. In proline, the chain bends back on itself to form a ring.

Yet all of these molecules have similar properties—they are all soluble in water, they are all both acidic and basic (amphoteric), they can all be joined with other amino acids to form proteins. This is because the chemistry of organic molecules depends much less on the number or the arrangement of carbon or hydrogen atoms than on the other types of atoms (O, N, S, P, Si…) in the molecule. We call parts of molecules containing small collections of these other atoms functional groups, simply because they are groups of atoms that determine the way the molecule works. All amino acids contain two functional groups: an amino (NH$_2$ or NH) group and a carboxylic acid (CO$_2$H) group (some contain other functional groups as well).

The functional groups determine the way the molecule works both chemically and biologically.
That isn’t to say the carbon atoms aren’t important; they just play quite a different role from those of the oxygen, nitrogen, and other atoms they are attached to. We can consider the chains and rings of carbon atoms we find in molecules as their skeletons, which support the functional groups and allow them to take part in chemical interactions, much as your skeleton supports your internal organs so they can interact with one another and work properly.

We will see later how the interpretation of organic structures as hydrocarbon frameworks supporting functional groups helps us to understand and rationalize the reactions of organic molecules. It also helps us to devise simple, clear ways of representing molecules on paper. You saw in Chapter 1 how we represented molecules on paper, and in the next section we shall teach you ways to draw (and ways not to draw) molecules—the handwriting of chemistry.

This section is extremely important, because it will teach you how to communicate chemistry, clearly and simply, throughout your life as a chemist.

Drawing molecules

Be realistic

Below is another organic structure—again, you may be familiar with the molecule it represents; it is a fatty acid commonly called linoleic acid.

We could also depict linoleic acid as

\[
\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}=\text{CHCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CO}_2\text{H}
\]

or as

X-ray crystallography discovers the structures of molecules by observing the way X-rays bounce off atoms in crystalline solids. It gives clear diagrams with the atoms marked as circles and the bonds as rods joining them together.
You can see that the chain of carbon atoms is not linear, but a zig-zag. Although our diagram is just a two-dimensional representation of this three-dimensional structure, it seems reasonable to draw it as a zig-zag too.

This gives us our first guideline for drawing organic structures.

---

**Guideline 1**

**Draw chains of atoms as zig-zags**

Realism of course has its limits—the X-ray structure shows that the linoleic acid molecule is in fact slightly bent in the vicinity of the double bonds; we have taken the liberty of drawing it as a ‘straight zig-zag’. Similarly, close inspection of crystal structures like this reveals that the angle of the zig-zag is about 109° when the carbon atom is not part of a double bond and 120° when it is. The 109° angle is the ‘tetrahedral angle’, the angle between two vertices of a tetrahedron when viewed from its centre. In Chapter 4 we shall look at why carbon atoms take up this particular arrangement of bonds. Our realistic drawing is a projection of a three-dimensional structure onto flat paper so we have to compromise.

**Be economical**

When we draw organic structures we try to be as realistic as we can be without putting in superfluous detail. Look at these three pictures.

1. is immediately recognizable as Leonardo da Vinci’s Mona Lisa. You may not recognize (2)—it’s also Leonardo da Vinci’s Mona Lisa—this time viewed from above. The frame is very ornate, but the picture tells us as much about the painting as our rejected linear and 90° angle diagrams did about
our fatty acid. They’re both correct—in their way—but sadly useless. What we need when we draw molecules is the equivalent of (3). It gets across the idea of the original, and includes all the detail necessary for us to recognize what it’s a picture of, and leaves out the rest. And it was quick to draw—this picture was drawn in less than 10 minutes: we haven’t got time to produce great works of art!

Because functional groups are the key to the chemistry of molecules, clear diagrams must emphasize the functional groups, and let the hydrocarbon framework fade into the background. Compare the diagrams below:

![Linoleic acid](image1)

The second structure is the way that most organic chemists would draw linoleic acid. Notice how the important carboxylic acid functional group stands out clearly and is no longer cluttered by all those Cs and Hs. The zig-zag pattern of the chain is much clearer too. And this structure is much quicker to draw than any of the previous ones!

To get this diagram from the one above we’ve done two things. Firstly, we’ve got rid of all the hydrogen atoms attached to carbon atoms, along with the bonds joining them to the carbon atoms. Even without drawing the hydrogen atoms we know they’re there—we assume that any carbon atom that doesn’t appear to have its potential for four bonds satisfied is also attached to the appropriate number of hydrogen atoms. Secondly, we’ve rubbed out all the Cs representing carbon atoms. We’re left with a zig-zag line, and we assume that every kink in the line represents a carbon atom, as does the end of the line.

We can turn these two simplifications into two more guidelines for drawing organic structures.

- **Guideline 2**
  Miss out the Hs attached to carbon atoms, along with the C–H bonds (unless there is a good reason not to)

- **Guideline 3**
  Miss out the capital Cs representing carbon atoms (unless there is a good reason not to)

**Be clear**

Try drawing some of the amino acids represented on p. 000 in a similar way, using the three guidelines. The bond angles at tetrahedral carbon atoms are about 109°. Make them look about 109° projected on to a plane! (120° is a good compromise, and it makes the drawings look neat.)

Start with leucine — earlier we drew it as the structure to the right. Get a piece of paper and do it now; then see how your drawing compares with our suggestions.
It doesn’t matter which way up you’ve drawn it, but your diagram should look something like one of these structures below.

![Structural diagrams](image)

The guidelines we gave were only guidelines, not rules, and it certainly does not matter which way round you draw the molecule. The aim is to keep the functional groups clear, and let the skeleton fade into the background. That’s why the last two structures are all right—the carbon atom shown as ‘C’ is part of a functional group (the carboxyl group) so it can stand out.

Now turn back to p. 000 and try redrawing the some of the other eight structures there using the guidelines. Don’t look at our suggestions below until you’ve done them! Then compare your drawings with our suggestions.

![Structural diagrams](image)

Remember that these are only suggestions, but we hope you’ll agree that this style of diagram looks much less cluttered and makes the functional groups much clearer than the diagrams on p. 000. Moreover, they still bear significant resemblance to the ‘real thing’—compare these crystal structures of lysine and tryptophan with the structures shown above, for example.

**Structural diagrams can be modified to suit the occasion**

You’ll probably find that you want to draw the same molecule in different ways on different occasions to emphasize different points. Let’s carry on using leucine as an example. We mentioned before that an amino acid can act as an acid or as a base. When it acts as an acid, a base (for example, hydroxide, OH⁻) removes H⁺ from the carboxylic acid group in a reaction we can represent as

\[
\text{leucine (acid form)} + \text{OH}^- \rightarrow \text{leucine (salt form)} + \text{H}_2\text{O}
\]

The product of this reaction has a negative charge on an oxygen atom. We have put it in a circle to make it clearer, and we suggest you do the same when you draw charges: +’s and −’s are easily mislaid. We shall discuss this type of reaction, the way in which reactions are drawn, and what the ‘curly arrows’ in the diagram mean in Chapter 5. But for now, notice that we drew out the CO₂H as the fragment left because we wanted to show how the O–H bond was broken when the base attacked. We modified our diagram to suit our own purposes.
When leucine acts as a base, the amino (NH₂) group is involved. The nitrogen atom attaches itself to a proton, forming a new bond using its *lone pair*.

We can represent this reaction as

![Diagram of the reaction](image)

Notice how we drew the lone pair at this time because we wanted to show how it was involved in the reaction. The oxygen atoms of the carboxylic acid groups also have lone pairs but we didn’t draw them in because they weren’t relevant to what we were talking about. Neither did we feel it was necessary to draw CO₂H in full this time because none of the atoms or bonds in the carboxylic acid functional group was involved in the reaction.

**Structural diagrams can show three-dimensional information on a two-dimensional page**

Of course, all the structures we have been drawing only give an idea of the real structure of the molecules. For example, the carbon atom between the NH₂ group and the CO₂H group of leucine has a tetrahedral arrangement of atoms around it, a fact which we have so far completely ignored.

We might want to emphasize this fact by drawing in the hydrogen atom we missed out at this point as in structure 1 (in the right-hand margin).

We can then show that one of the groups attached to this carbon atom comes towards us, out of the plane of the paper, and the other one goes away from us, into the paper. There are several ways of doing this. In structure 2, the bold, wedged bond suggests a perspective view of a bond coming towards you, while the hashed bond suggests a bond fading away from you. The other two ‘normal’ bonds are in the plane of the paper.

Alternatively we could miss out the hydrogen atom and draw something a bit neater though slightly less realistic as structure 3.

We can assume the missing hydrogen atom is behind the plane of the paper, because that is where the ‘missing’ vertex of the tetrahedron of atoms attached to the carbon atom lies. These conventions allow us to give an idea of the three-dimensional shape (stereochemistry) of any organic molecule—you have already seen them in use in the diagram of the structure of palytoxin at the beginning of this chapter.

---

**Reminder**

*Organic structures should be drawn to be realistic, economical, clear.*

We gave three guidelines to help you achieve this when you draw structures:

- **Guideline 1:** Draw chains of atoms as zig-zags
- **Guideline 2:** Miss out the Hs attached to carbon atoms, along with the C–H bonds
- **Guideline 3:** Miss out the capital Cs representing carbon atoms

---

The guidelines we have given and conventions we have illustrated in this section have grown up over decades. They are used by organic chemists because they work! We guarantee to follow them for the rest of the book—try to follow them yourself whenever you draw an organic structure. Before you ever draw a capital C or a capital H again, ask yourself whether it’s really necessary!

Now that we have considered how to draw structures, we can return to some of the structural types that we find in organic molecules. Firstly, we’ll talk about hydrocarbon frameworks, then about functional groups.
Hydrocarbon frameworks

Carbon as an element is unique in the variety of structures it can form. It is unusual because it forms strong, stable bonds to the majority of elements in the periodic table, including itself. It is this ability to form bonds to itself that leads to the variety of organic structures that exist, and indeed to the possibility of life existing at all. Carbon may make up only 0.2% of the earth’s crust, but it certainly deserves a whole branch of chemistry all to itself.

Chains

The simplest class of hydrocarbon frameworks contains just chains of atoms. The fatty acids we met earlier have hydrocarbon frameworks made of zig-zag chains of atoms, for example. Polythene is a polymer whose hydrocarbon framework consists entirely of chains of carbon atoms.

A section of the structure of polythene

At the other end of the spectrum of complexity is this antibiotic, extracted from a fungus in 1995 and aptly named linearmycin as it has a long linear chain. The chain of this antibiotic is so long that we have to wrap it round two corners just to get it on the page.

Names for carbon chains

It is often convenient to refer to a chain of carbon atoms by a name indicating its length. You have probably met some of these names before in the names of the simplest organic molecules, the alkanes. There are also commonly used abbreviations for these names: these can be very useful in both writing about chemistry and in drawing chemical structures, as we shall see shortly.

Organic elements

You may notice that the abbreviations for the names of carbon chains look very much like the symbols for chemical elements: this is deliberate, and these symbols are sometimes called ‘organic elements’. They can be used in chemical structures just like element symbols. It is often convenient to use the ‘organic element’ symbols for short carbon chains for tidiness. Here are some examples. Structure 1 to the right shows how we drew the structure of the amino acid methionine on p. 24. The stick representing the methyl group attached to the sulfur atom does, however, look a little odd. Most chemists would draw methionine as structure 2, with ‘Me’ representing the CH$_3$ (methyl) group. Tetraethyllead used to be added to petrol to prevent engines ‘knocking’, until it was shown to be a health hazard. Its structure (as you might easily guess from the name) is shown as item 3. But it’s much easier to write as PbEt$_4$ or Et$_4$Pb.

Remember that these symbols (and names) can only be used for terminal chains of atoms. We couldn’t abbreviate the structure of lysine from

![Lysine structure](image)

for example, because Bu represents

![Butyl structure](image)

and not

![Butyl structure](image)

Before leaving carbon chains, we must mention one other very useful organic element symbol, R. R in a structure can mean anything—it’s a sort of wild card. For example, structure 4 would indicate any amino acid, where R = H is glycine, R = Me is alanine… As we’ve mentioned before, and you will see later, the reactivity of organic molecules is so dependent on their functional groups that the rest of the molecule can be irrelevant. In these cases, we can choose just to call it R.

Carbon rings

Rings of atoms are also common in organic structures. You may have heard the famous story of Auguste Kekulé first realizing that benzene has a ring structure when he dreamed of snakes biting their own tails. You have met benzene rings in phenylalanine and aspirin. Paracetamol also has a structure based on a benzene ring.

![Benzene structure](image)

When a benzene ring is attached to a molecule by only one of its carbon atoms (as in phenylalanine, but not paracetamol or aspirin), we can call it a ‘phenyl’ group and give it the organic element symbol Ph.

![Phenyl group structure](image)

**Benzene has a ring structure**

In 1865, August Kekulé presented a paper at the Academie des Sciences in Paris suggesting a cyclic structure for benzene, the inspiration for which he ascribed to a dream. However, was Kekulé the first to suggest that benzene was cyclic? Some believe not, and credit an Austrian schoolteacher, Josef Loschmidt with the first depiction of cyclic benzene structures. In 1861, 4 years before Kekulé’s dream, Loschmidt published a book in which he represented benzene as a set of rings. It is not certain whether Loschmidt or Kekulé—or even a Scot named Archibald Couper—got it right first.
Any compound containing a benzene ring, or a related (Chapter 7) ring system is known as ‘aromatic’, and another useful organic element symbol related to Ph is Ar (for ‘aryl’). While Ph always means C₆H₅, Ar can mean any substituted phenyl ring, in other words, phenyl with any number of the hydrogen atoms replaced by other groups.

For example, while PhOH always means phenol, ArOH could mean phenol, 2,4,6-trichlorophenol (the antiseptic TCP), paracetamol or aspirin (among many other substituted phenols). Like R, the ‘wild card’ alkyl group, Ar is a ‘wild card’ aryl group.

The compound known as muscone has only relatively recently been made in the lab. It is the pungent aroma that makes up the base-note of musk fragrances. Before chemists had determined its structure and devised a laboratory synthesis the only source of musk was the musk deer, now rare for this very reason. Muscone’s skeleton is a 13-membered ring of carbon atoms.

The steroid hormones have several (usually four) rings fused together. These are testosterone and oestradiol, the important human male and female sex hormones.

Some ring structures are much more complicated. The potent poison strychnine is a tangle of interconnecting rings.

One of the most elegant ring structures is shown above and is known as Buckminsterfullerene. It consists solely of 60 carbon atoms in rings that curve back on themselves to form a football-shaped cage.

Count the number of bonds at any junction and you will see they add up to four so no hydrogens need be added. This compound is C₆₀. Note that you can’t see all the atoms as some are behind the sphere.

Rings of carbon atoms are given names starting with ‘cyclo’, followed by the name for the carbon chain with the same number of carbon atoms.
To the right, structure 1 shows chrysanthemic acid, part of the naturally occurring pesticides called pyrethrins (an example appears in Chapter 1), which contains a cyclopropane ring. Propane has three carbon atoms. Cyclopropane is a three-membered ring. Grandisol (structure 2), an insect pheromone used by male boll weevils to attract females, has a structure based on a cyclobutane ring. Butane has four carbon atoms. Cyclobutane is a four-membered ring. Cyclamate (structure 3), formerly used as an artificial sweetener, contains a cyclohexane ring. Hexane has six carbon atoms. Cyclohexane is a six-membered ring.

**Branches**

Hydrocarbon frameworks rarely consist of single rings or chains, but are often branched. Rings, chains, and branches are all combined in structures like that of the marine toxin palytoxin that we met at the beginning of the chapter, polystyrene, a polymer made of six-membered rings dangling from linear carbon chains, or of β-carotene, the compound that makes carrots orange.

Just like some short straight carbon chains, some short branched carbon chains are given names and organic element symbols. The most common is the isopropyl group. Lithium diisopropylamide (also called LDA) is a strong base commonly used in organic synthesis.

Iproniazid is an antidepressant drug with i-Pr in both structure and name. Notice how the ‘propyl’ part of ‘isopropyl’ still indicates three carbon atoms; they are just joined together in a different way—in other words, as an isomer of the straight chain propyl group. Sometimes, to avoid confusion, the straight chain alkyl groups are called ‘n-alkyl’ (for example, n-Pr, n-Bu)—n for ‘normal’—to distinguish them from their branched counterparts.

**Isomers** are molecules with the same kinds and numbers of atoms joined up in different ways. n-propanol, n-PrOH, and isopropanol, i-PrOH, are isomeric alcohols. Isomers need not have the same functional groups, these compounds are all isomers of C₄H₈O.
The isobutyl (i-Bu) group is a CH₂ group joined to an i-Pr group. It is \( i\text{-PrCH}_2\) –
Two isobutyl groups are present in the reducing agent diisobutyl aluminium hydride (DIBAL).

\[
\text{diisobutyl aluminium hydride (DIBAL) is equivalent to } \text{HAl-Bu}_2
\]

The painkiller ibuprofen (marketed as Nurofen\textsuperscript{®}) contains an isobutyl group.

There are two more isomers of the butyl group, both of which have common names and abbreviations. The \( s\)-butyl group (\( s\)-butyl or \( s\)-Bu) has a methyl and an ethyl group joined to the same carbon atom. It appears in an organolithium compound, \( s\)-butyl lithium, used to introduce lithium atoms into organic molecules.

The \( t\)-butyl group (\( t\)-butyl or \( t\)-Bu) group has three methyl groups joined to the same carbon atom. Two \( t\)-Bu groups are found in BHT ('butylated hydroxy toluene'), an antioxidant added to some processed foods.

\[
\text{The prefixes } s\text{- and } t\text{- are really short for secondary and tertiary, terms that refer to the carbon atom that attaches these groups to the rest of the molecular structure.}
\]

- **Primary, secondary, and tertiary**

  The prefixes \( s\)- and \( t\)- are really short for secondary and tertiary, terms that refer to the carbon atom that attaches these groups to the rest of the molecular structure.

  - methyl (no attached C)
  - primary (1 attached C)
  - secondary (2 attached C)
  - tertiary (3 attached C)
  - quaternary (4 attached C)

  A primary carbon atom is attached to only one other C atom, a secondary to two other C atoms, and so on. This means there are five types of carbon atom.

  These names for bits of hydrocarbon framework are more than just useful ways of writing or talking about chemistry. They tell us something fundamental about the molecule and we shall use them when we describe reactions.
This quick architectural tour of some of the molecular edifices built by nature and by man serves just as an introduction to some of the hydrocarbon frameworks you will meet in the rest of this chapter and of this book. Yet, fortunately for us, however complicated the hydrocarbon framework might be, it serves only as a support for the functional groups. And, by and large, a functional group in one molecule behaves in much the same way as it does in another molecule. What we now need to do, and we start in the next section, is to introduce you to some functional groups, and to explain why it is that their attributes are the key to understanding organic chemistry.

**Functional groups**

If you can take ethane gas (CH\(_3\)CH\(_3\), or EtH, or even \(\text{CH}_3\text{CH}_3\), though a single line like this doesn’t look much like a chemical structure) and bubble it through acids, bases, oxidizing agents, reducing agents—in fact almost any chemical you can think of—it will remain unchanged. Just about the only thing you can do with it is burn it. Yet ethanol (CH\(_3\)CH\(_2\)OH, or EtOH, or preferably EtOH) not only burns, it reacts with acids, bases, and oxidizing agents.

The difference between ethanol and ethane is the functional group—the OH or hydroxyl group. We know that these chemical properties (being able to react with acids, bases, and oxidizing agents) are properties of the hydroxyl group and not just of ethanol because other compounds containing OH groups (in other words, other alcohols) have similar properties, whatever their hydrocarbon frameworks.

Your understanding of functional groups will be the key to your understanding of organic chemistry. We shall therefore now go on to meet some of the most important functional groups. We won’t say much about the properties of each group; that will come in Chapter 5 and later. Your task at this stage is to learn to recognize them when they appear in structures, so make sure you learn their names. The classes of compound associated with some functional groups also have names: for example, compounds containing the hydroxyl group are known as alcohols. Learn these names too as they are more important than the systematic names of individual compounds.

We’ve told you a few snippets of information about each group to help you to get to know something of the group’s character.

**Alkanes contain no functional groups**

The alkanes are the simplest class of organic molecules because they contain no functional groups. They are extremely unreactive, and therefore rather boring as far as the organic chemist is concerned. However, their unreactivity can be a bonus, and alkanes such as pentane and hexane are often used as solvents, especially for purification of organic compounds. Just about the only thing alkanes will do is burn—methane, propane, and butane are all used as domestic fuels, and petrol is a mixture of alkanes containing largely isooctane.

**Alkenes (sometimes called olefins) contain C=C double bonds**

It may seem strange to classify a type of bond as a functional group, but you will see later that C=C double bonds impart reactivity to an organic molecule just as functional groups consisting of, say, oxygen or nitrogen atoms do. Some of the compounds produced by plants and used by perfumers are alkenes (see Chapter 1). For example, pinene has a smell evocative of pine forests, while limonene smells of citrus fruits.

**Ethanol**

The reaction of ethanol with oxidizing agents makes vinegar from wine and sober people from drunk ones. In both cases, the oxidizing agent is oxygen from the air, catalysed by an enzyme in a living system. The oxidation of ethanol by microorganisms that grow in wine left open to the air leads to acetic acid (ethanoic acid) while the oxidation of ethanol by the liver gives acetaldehyde (ethanal).

**Human metabolism and oxidation**

The human metabolism makes use of the oxidation of alcohols to render harmless other toxic compounds containing the OH group. For example, lactic acid, produced in muscles during intense activity, is oxidized by an enzyme called lactate dehydrogenase to the metabolically useful compound pyruvic acid.
You’ve already met the orange pigment β-carotene. Eleven C=C double bonds make up most of its structure. Coloured organic compounds often contain chains of C=C double bonds like this. In Chapter 7 you will find out why this is so.

Alkynes contain C≡C triple bonds
Just like C=C double bonds, C≡C triple bonds have a special type of reactivity associated with them, so it’s useful to call a C≡C triple bond a functional group. Alkynes are linear so we draw them with four carbon atoms in a straight line. Alkynes are not as widespread in nature as alkenes, but one fascinating class of compounds containing C≡C triple bonds is a group of antitumour agents discovered during the 1980s. Calicheamicin is a member of this group. The high reactivity of this combination of functional groups enables calicheamicin to attack DNA and prevent cancer cells from proliferating. For the first time we have drawn a molecule in three dimensions, with two bonds crossing one another—can you see the shape?

Alcohols (R–OH) contain a hydroxyl (OH) group
We’ve already talked about the hydroxyl group in ethanol and other alcohols. Carbohydrates are peppered with hydroxyl groups; sucrose has eight of them for example (a more three-dimensional picture of the sucrose molecule appears in Chapter 1).

Molecules containing hydroxyl groups are often soluble in water, and living things often attach sugar groups, containing hydroxyl groups, to otherwise insoluble organic compounds to keep them in solution in the cell. Calicheamicin, a molecule we have just mentioned, contains a string of sugars for just this reason. The liver carries out its task of detoxifying unwanted organic compounds by repeatedly hydroxylating them until they are water-soluble, and they are then excreted in the bile or urine.

Ethers (R¹–O–R²) contain an alkoxy group (–OR)
The name ether refers to any compound that has two alkyl groups linked through an oxygen atom. ‘Ether’ is also used as an everyday name for diethyl ether, Et₂O. You might compare this use of the word ‘ether’ with the common use of the word ‘alcohol’ to mean ethanol. Diethyl ether is a highly flammable solvent that boils at only 35 °C. It used to be used as an anaesthetic. Tetrahydrofuran (THF) is another commonly used solvent and is a cyclic ether.

Brevetoxin B is a fascinating naturally occurring compound that was synthesized in the laboratory in 1995. It is packed with ether functional groups in ring sizes from 6 to 8.
Amines (R–NH₂) contain the amino (NH₂) group
We met the amino group when we were discussing the amino acids: we mentioned that it was this group that gave these compounds their basic properties. Amines often have powerful fishy smells: the smell of putrescine is particularly foul. It is formed as meat decays. Many neurologically active compounds are also amines: amphetamine is a notorious stimulant.

Nitro compounds (R–NO₂) contain the nitro group (NO₂)
The nitro group (NO₂) is often incorrectly drawn with five bonds to nitrogen which you will see in Chapter 4, is impossible. Make sure you draw it correctly when you need to draw it out in detail. If you write just NO₂ you are all right!

Several nitro groups in one molecule can make it quite unstable and even explosive. Three nitro groups give the most famous explosive of all, TNT (trinitrotoluene), its kick.

However, functional groups refuse to be stereotyped. Nitrazepam also contains a nitro group, but this compound is marketed as Mogadon®, the sleeping pill.

Alkyl halides (fluorides R–F, chlorides R–Cl, bromides R–Br, or iodides R–I) contain the fluoro, chloro, bromo, or iodo groups
These three functional groups have similar properties—though alkyl iodides are the most reactive and alkyl fluorides the least. PVC (polyvinyl chloride) is one of the most widely used polymers—it has a chloro group on every other carbon atom along a linear hydrocarbon framework. Methyl iodide (MeI), on the other hand, is a dangerous carcinogen, since it reacts with DNA and can cause mutations in the genetic code.
Aldehydes (R–CHO) and ketones (R¹–CO–R²) contain the carbonyl group C=O

Aldehydes can be formed by oxidizing alcohols—in fact the liver detoxifies ethanol in the bloodstream by oxidizing it first to acetaldehyde (ethanal, CH₃CHO). Acetaldehyde in the blood is the cause of hangovers. Aldehydes often have pleasant smells—2-methylundecanal is a key component of the fragrance of Chanel No 5™, and ‘raspberry ketone’ is the major component of the flavour and smell of raspberries.

Carboxylic acids (R–CO₂H) contain the carboxyl group CO₂H

As their name implies, compounds containing the carboxylic acid (CO₂H) group can react with bases, losing a proton to form carboxylate salts. Edible carboxylic acids have sharp flavours and several are found in fruits—citric, malic, and tartaric acids are found in lemons, apples, and grapes, respectively.

Esters (R¹–CO₂R²) contain a carboxyl group with an extra alkyl group (CO₂R)

Fats are esters; in fact they contain three ester groups. They are formed in the body by condensing glycerol, a compound with three hydroxyl groups, with three fatty acid molecules.

Other, more volatile esters, have pleasant, fruity smells and flavours. These three are components of the flavours of bananas, rum, and apples:

Amides (R–CONH₂, R¹–CONHR², or R¹CONR²R³)

Proteins are amides: they are formed when the carboxylic acid group of one amino acid condenses with the amino group of another to form an amide linkage (also known as a peptide bond). One protein molecule can contain hundreds of amide bonds. Aspartame, the artificial sweetener marketed as NutraSweet®, on the other hand contains just two amino acids, aspartic acid and phenylalanine, joined through one amide bond. Paracetamol is also an amide.
Nitriles or cyanides (R–CN) contain the cyano group –C≡N
Nitrile groups can be introduced into molecules by reacting potassium cyanide with alkyl halides. The organic nitrile group has quite different properties associated with lethal inorganic cyanide: Laetrile, for example, is extracted from apricot kernels, and was once developed as an anticancer drug. It was later proposed that the name be spelt ‘liar-trial’ since the results of the clinical trials on laetrile turned out to have been falsified!

Acyl chlorides (acid chlorides) (R–COCl)
Acyl chlorides are reactive compounds used to make esters and amides. They are derivatives of carboxylic acids with the –OH replaced by –Cl, and are too reactive to be found in nature.

Acetals
Acetals are compounds with two single bonded oxygen atoms attached to the same carbon atom. Many sugars are acetals, as is laetrile which you have just met.

Carbon atoms carrying functional groups can be classified by oxidation level
All functional groups are different, but some are more different than others. For example, the structures of a carboxylic acid, an ester, and an amide are all very similar: in each case the carbon atom carrying the functional group is bonded to two heteroatoms, one of the bonds being a double bond. You will see in Chapter 12 that this similarity in structure is mirrored in the reactions of these three types of compounds, and in the ways in which they can be interconverted. Carboxylic acids, esters, and amides can be changed one into another by reaction with simple reagents or reducing agents. A reducing agent (a reagent which adds hydrogen atoms). We say that the carbon atoms carrying functional groups that can be interconverted without the need for reducing agents (or oxidizing agents) have the same oxidation level—in this case, we call it the ‘carboxylic acid oxidation level’.

In fact, amides can quite easily be converted into nitriles just by dehydration (removal of water), so we must give nitrile carbon atoms the same oxidation level as carboxylic acids, esters, and amides. Maybe you’re beginning to see the structural similarity between these four functional groups that you could have used to assign their oxidation level? In all four cases, the carbon atom has three bonds to heteroatoms, and only one to C or H. It doesn’t matter how many heteroatoms there are, just how many bonds to them. Having noticed this, we can also assign both carbon atoms in ‘CFC-113’, one of the environmentally unfriendly aerosol propellants/refrigerants that have caused damage to the earth’s ozone layer, to the carboxylic acid oxidation level.

Aldehydes and ketones contain a carbon atom with two bonds to heteroatoms; they are at the ‘aldehyde oxidation level’. The common laboratory solvent dichloromethane also has two bonds to heteroatoms, so it too contains a carbon atom at the aldehyde oxidation level, as do acetals.
Alcohols, ethers, and alkyl halides have a carbon atom with only one single bond to a heteroatom. We assign these the ‘alcohol oxidation level’, and they are all easily made from alcohols without oxidation or reduction.

Lastly, we must include simple alkanes, which have no bonds to heteroatoms, as an ‘alkane oxidation level’.

The small class of compounds that have a carbon atom with four bonds to heteroatoms is related to CO₂ and best described as at the carbon dioxide oxidation level.

Alkenes and alkynes obviously don’t fit easily into these categories as they have no bonds to het-
eroatoms. Alkenes can be made from alcohols by dehydration without any oxidation or reduction so
it seems sensible to put them in the alcohol column. Similarly, alkynes and aldehydes are related by
hydration/dehydration without oxidation or reduction.

**Naming compounds**

So far, we have talked a lot about compounds by name. Many of the names we’ve used (palytoxin,
muscone, brevetoxin…) are simple names given to complicated molecules without regard for the
actual structure or function of the molecule—these three names, for example, are all derived from
the name of the organism from which the compound was first extracted. They are known as trivial
names, not because they are unimportant, but because they are used in everyday scientific conversa-
tion.

Names like this are fine for familiar compounds that are widely used and referred to by chemists,
biologists, doctors, nurses, perfumers alike. But there are over 16 million known organic com-
ponds. They can’t all have simple names, and no one would remember them if they did. For this
reason, the IUPAC (International Union of Pure and Applied Chemistry) have developed systemat-
ic nomenclature, a set of rules that allows any compound to be given a unique name that can be
deduced directly from its chemical structure. Conversely, a chemical structure can be deduced from
its systematic name.

The problem with systematic names is that they tend to be grotesquely unpronounceable for any-
thing but the most simple molecules. In everyday speech and writing, chemists therefore do tend to
disregard them, and use a mixture of systematic and trivial names. Nonetheless, it’s important to
know how the rules work. We shall look next at systematic nomenclature, before going on to look at
the real language of chemistry.

**Systematic nomenclature**

There isn’t space here to explain all the rules for giving systematic names for compounds—they fill
several desperately dull volumes, and there’s no point knowing them anyway since computers will do
the naming for you. What we will do is to explain the principles underlying systematic nomencla-
ture. You should understand these principles, because they provide the basis for the names used by
chemists for the vast majority of compounds that do not have their own trivial names.

Systematic names can be divided into three parts: one describes the hydrocarbon framework; one
describes the functional groups; and one indicates where the functional groups are attached to the
skeleton.

You have already met the names for some simple fragments of hydrocarbon framework (methyl,
etyl, propyl…). Adding a hydrogen atom to these alkyl fragments and changing -yl to -ane makes
the alkanes and their names. You should hardly need reminding of their structures:

**Names for the hydrocarbon framework**

</tr>
<tr>
<td></td>
<td>Cyclopropane</td>
<td>( \triangle )</td>
</tr>
</tbody>
</table>
The name of a functional group can be added to the name of a hydrocarbon framework either as a suffix or as a prefix. Some examples follow. It is important to count all of the carbon atoms in the chain, even if one of them is part of a functional group: so pentanenitrile is actually BuCN.

Compounds with functional groups attached to a benzene ring are named in a similar way. Numbers are used to locate functional groups

Sometimes a number can be included in the name to indicate which carbon atom the functional group is attached to. None of the above list needed a number—check that you can see why not for each one. When numbers are used, the carbon atoms are counted from one end. In most cases, either of two numbers could be used (depending on which end you count from); the one chosen is always the lower of the two. Again, some examples will illustrate this point. Notice again that some functional groups are named by prefixes, some by suffixes, and that the number always goes directly before the functional group name.
Here are some examples of compounds with more than one functional group.

Again, the numbers indicate how far the functional groups are from the end of the carbon chain. Counting must always be from the same end for each functional group. Notice how we use di-, tri-, tetra- if there are more than one of the same functional group.

With cyclic compounds, there isn’t an end to the chain, but we can use numbers to show the distance between the two groups—start from the carbon atom carrying one of the functional groups, then count round.

These rules work for hydrocarbon frameworks that are chains or rings, but many skeletons are branched. We can name these by treating the branch as though it were a functional group:

**Ortho, meta, and para**

With substituted benzene rings, an alternative way of identifying the positions of the substituents is to use the terms ortho, meta, and para. Ortho compounds are 1,2-disubstituted, meta compounds are 1,3-disubstituted, and para compounds are 1,4-disubstituted. Some examples should make this clear. ortho, meta, and para are often abbreviated to o, m, and p.
The terms ortho, meta, and para are used by chemists because they’re easier to remember than numbers, and the words carry with them chemical meaning. ‘Ortho’ shows that two groups are next to each other on the ring even though the atoms may not happen to be numbered 1 and 2. They are one example of the way in which chemists don’t always use systematic nomenclature but revert to more convenient ‘trivial’ terms. We consider trivial names in the next section.

What do chemists really call compounds?

The point of naming a compound is to be able to communicate with other chemists. Most chemists are happiest communicating chemistry by means of structural diagrams, and structural drawings are far more important than any sort of chemical nomenclature. That’s why we explained in detail how to draw structures, but only gave an outline of how to name compounds. Good diagrams are easy to understand, quick to draw, and difficult to misinterpret.

But we do need to be able to communicate by speech and by writing as well. In principle we could do this by using systematic names. In practice, though, the full systematic names of anything but the simplest molecules are far too clumsy for use in everyday chemical speech. There are several alternatives, mostly based on a mixture of trivial and systematic names.

Names for well known and widely used simple compounds

A few simple compounds are called by trivial names not because the systematic names are complicated, but just out of habit. We know them so well that we use their familiar names.

You may have met this compound before (left), and perhaps called it ethanoic acid, its systematic name. But in a chemical laboratory, everyone would refer to this acid as acetic acid, its trivial name. The same is true for all these common substances.

Trivial names like this are often long-lasting, well understood historical names that are less easy to confuse than their systematic counterparts. ‘Acetaldehyde’ is easier to distinguish from ‘ethanol’ than is ‘ethanal’.

Trivial names also extend to fragments of structures containing functional groups. Acetone, acetaldehyde, and acetic acid all contain the acetyl group (MeCO-, ethanoyl) abbreviated Ac and chemists often use this ‘organic element’ in writing AcOH for acetic acid or EtOAc for ethyl acetate.

Chemists use special names for four fragments because they have mechanistic as well as structural significance. These are vinyl and allyl; phenyl and benzyl.
Giving the vinyl group a name allows chemists to use simple trivial names for compounds like vinyl chloride, the material that polymerizes to give PVC (poly vinyl chloride) but the importance of the name lies more in the difference in reactivity (Chapter 17) between vinyl and allyl groups.

The allyl group gets its name from garlic (*Allium* sp.), because it makes up part of the structure of the compounds responsible for the taste and smell of garlic.

Allyl and vinyl are different in that the vinyl group is attached directly to a double bonded C=C carbon atom, while the allyl group is attached to a carbon atom adjacent to the C=C double bond. The difference is extremely important chemically: allyl compounds are typically quite reactive, while vinyl compounds are fairly unreactive.

For some reason, the allyl and vinyl groups have never acquired organic element symbols, but the benzyl group has and is called Bn. It is again important not to confuse the benzyl group with the phenyl group: the phenyl group is joined through a carbon atom in the ring, while the benzyl group is joined through a carbon atom attached to the ring. Phenyl compounds are typically unreactive but benzyl compounds are often reactive. Phenyl is like vinyl and benzyl is like allyl.

We shall review all the organic element element symbols you have met at the end of the chapter.

### Names for more complicated but still well known molecules

Complicated molecules that have been isolated from natural sources are always given trivial names, because in these cases, the systematic names really are impossible!

Strychnine is a famous poison featured in many detective stories and a molecule with a beautiful structure. All chemists refer to it as strychnine as the systematic name is virtually unpronounceable. Two groups of experts at IUPAC and *Chemical Abstracts* also have different ideas on the systematic name for strychnine. Others like this are penicillin, DNA, and folic acid.

But the champion is vitamin B<sub>12</sub>, a complicated cobalt complex with a three-dimensional structure of great intricacy. No chemist would learn this structure but would look it up in an advanced textbook of organic chemistry. You will find it in such books in the index under vitamin B<sub>12</sub> and not under its systematic name. We do not even know what its systematic name might be and we are not very interested. This is vitamin B<sub>12</sub>.

Even fairly simple but important molecules, the amino acids for example, that have systematic names that are relatively easy to understand are normally referred to by their trivial names.
trivial names which are, with a bit of practice, easy to remember and hard to muddle up. They are
given in full in Chapter 49.

\[
\begin{align*}
\text{alanine, or} & \quad \text{2-aminopropanoic acid} \\
\text{leucine, or} & \quad \text{2-amino-4-methylpentanoic acid} \\
\text{lysine, or} & \quad \text{2,6-diaminohexanoic acid}
\end{align*}
\]

A very flexible way of getting new, simple names for compounds can be to combine a bit of sys-
tematic nomenclature with trivial nomenclature.

Alanine is a simple amino acid that occurs in proteins. Add a phenyl group and you have phenyl-
lalanine a more complex amino acid also in proteins.

Toluene, the common name for methylbenzene, can be combined (both chemically and in mak-
ing names for compounds!) with three nitro groups to give the famous explosive trinitrotoluene or
TNT.

Compounds named as acronyms

Some compounds are referred to by acronyms, shortened versions of either their systematic or their triv-
ial name. We just saw TNT as an abbreviation for TriNitroToluene but the commoner use for acronyms
is to define solvents and reagents in use all the time. Later in the book you will meet these solvents.

![The names and structures of these common solvents need learning too.]

The following reagents are usually referred to by acronym and their functions will be introduced
in other chapters so you do not need to learn them now. You may notice that some acronyms refer to
trivial and some to systematic names. There is a glossary of acronyms for solvents, reagents, and
other compounds on p. 000.

LDA
\text{Lithium Di-isopropyl Amide}

DIBAL
\text{Di-isoButylAluminiumhydride}

PCC
\text{Pyridinium Chlorochromate}

DEAD
\text{DiEthyl Azo-Dicarboxylate}

Compounds for which chemists use systematic names

You may be surprised to hear that practising organic chemists use systematic names at all in view of
what we have just described, but they do! Systematic names really begin with derivatives of pentane
\((C_5H_{12})\) since the prefix pent- means five, whereas but- does not mean four. Chemists refer to sim-
ple derivatives of open chain and cyclic compounds with 5 to about 20 carbon atoms by their system-
atic names, providing that there is no common name in use. Here are some examples.

- cyclopentadiene
- cyclo-octa-1,5-diene
- cyclocodeca-1,5,9-triene
- 2,7-dimethyl-3,5-octadiyne-2,7-diol
These names contain a syllable that tells you the framework size: penta- for C₅, octa- for C₈, nona- for C₉, undeca- for C₁₁, and dodeca- for C₁₂. These names are easily worked out from the structures and, what is more important, you get a clear idea of the structure from the name. One of them might make you stop and think a bit (which one?), but the others are clear even when heard without a diagram to look at.

Complicated molecules with no trivial names

When chemists make complex new compounds in the laboratory, they publish them in a chemical journal giving their full systematic names in the experimental account, however long and clumsy those names may be. But in the text of the paper, and while talking in the lab about the compounds they have made, they will just call them ‘the amine’ or ‘the alkene’. Everyone knows which amine or alkene is meant because at some point they remember seeing a chemical structure of the compound. This is the best strategy for talking about almost any molecule: draw a structure, then give the compound a ‘tag’ name like ‘the amine’ or ‘the acid’. In written chemistry it’s often easiest to give every chemical structure a ‘tag’ number as well.

To illustrate what we mean, let’s talk about this compound.

This carboxylic acid was made and used as an intermediate when chemists in California made brevetoxin (see p. 000) in 1995. Notice how we can call a complicated molecule ‘this acid’—a ‘tag’ name—because you’ve seen the structure. It also has a tag number (19), so we can also call it ‘compound 19’, or ‘acid 19’, or ‘brevetoxin fragment 19’. How much more sensible than trying to work out its systematic name.

How should you name compounds?

So what should you call a compound? It really depends on circumstances, but you won’t go far wrong if you follow the example of this book. We shall use the names for compounds that real

---

### Our advice on chemical names—six points in order of importance

- Draw a structure first and worry about the name afterwards
- Learn the names of the functional groups (ester, nitrile, etc.)
- Learn and use the names of a few simple compounds used by all chemists
- In speech, refer to compounds as ‘that acid’ (or whatever) while pointing to a diagram
- Grasp the principles of systematic (IUPAC) nomenclature and use it for compounds of medium size
- Keep a notebook to record acronyms, trivial names, structures, etc. that you might need later
chemists use. There’s no need to learn all the commonly used names for compounds now, but you should log them in your memory as you come across them. Never allow yourself to pass a compound name by unless you are sure you know what chemical structure it refers to. You will find many of the commonly used names for compounds on the endpapers of this book. Refer to these, or to the shorter glossary on p. 000 to refresh your memory should you ever need to.

We’ve met a great many molecules in this chapter. Most of them were just there to illustrate points so don’t learn their structures! Instead, learn to recognize the names of the functional groups they contain. However, there were 10 names for simple compounds and three for common solvents that we advised you to learn. Cover up the structures on the rest of this page and draw the structures for these 13 compounds.

That’s all we’ll say on the subject of nomenclature—you’ll find that as you practise using these names and start hearing other people referring to compounds by name you’ll soon pick up the most important ones. But, to reiterate, make sure you never pass a compound name by without being absolutely sure what it refers to—draw a structure to check.
1. Draw good diagrams of saturated hydrocarbons with seven carbon atoms having (a) linear, (b) branched, and (c) cyclic frameworks. Draw molecules based on each framework having both ketone and carboxylic acid functional groups.

2. Study the structure of brevetoxin on p. 000. Make a list of the different types of functional group (you already know that there are many ethers) and of the numbers of rings of different sizes. Finally study the carbon framework—is it linear, cyclic, or branched?

3. What is wrong with these structures? Suggest better ways of representing these molecules.

4. Draw structures corresponding to these names. In each case suggest alternative names that might convey the structure more clearly to someone who is listening to you speak.
   (a) 1,4-di-1(1-dimethylethyl)benzene
   (b) 2-(prop-2-enyloxy)prop-1-ene
   (c) cyclohexa-1,3,5-triene

5. Draw one possible structure for each of these molecules, selecting any group of your choice for the ‘wild card’ substituents.

6. Translate these very poor ‘diagrams’ of molecules into more realistic structures. Try to get the angles about right and, whatever you do, don’t include any square coplanar carbon atoms or other bond angles of 90°!

7. Suggest at least six different structures that would fit the formula C₆H₇NO. Make good realistic diagrams of each one and say which functional group(s) are present.

8. Draw and name a structure corresponding to each of these descriptions.
   (a) An aromatic compound containing one benzene ring with the following substituents: two chlorine atoms having a para relationship, a nitro group having an ortho relationship to one of the chlorine atoms, and an acetyl group having a meta relationship to the nitro group.
An alkyne having a trifluoromethyl substituent at one end and a chain of three carbon atoms at the other with a hydroxyl group on the first atom, an amino group on the second, and the third being a carboxyl group.

9. Draw full structures for these compounds, displaying the hydrocarbon framework clearly and showing all the bonds present in the functional groups. Name the functional groups.

- AcO(CH₂)₃NO₂
- MeO₂C.CH₂.COEt
- CH₂=CH.CO.NH(CH₂)₂CN

10. Identify the oxidation level of each of the carbon atoms in these structures with some sort of justification.

11. If you have not already done so, complete the exercises on pp. 000 (drawing amino acids) and 000 (giving structures for the 10 common compounds and three common solvents).
Determining organic structures

Introduction

Organic structures can be determined accurately and quickly by spectroscopy

Having urged you, in the last chapter, to draw structures realistically, we now need to answer the question: what is realistic? How do we know what structures molecules actually have? Make no mistake about this important point: we really do know what shape molecules have. You wouldn’t be far wrong if you said that the single most important development in organic chemistry in modern times is just this certainty, as well as the speed with which we can be certain. What has caused this revolution can be stated in a word—spectroscopy.

Structure of the chapter

We shall first consider structure determination as a whole and then introduce three different methods:

- Mass spectrometry (to determine mass of molecule and atomic composition)
- Nuclear magnetic resonance (NMR) spectroscopy (to determine carbon skeleton of molecule)
- Infrared spectroscopy (to determine functional groups in molecule)

Of these, NMR is more important than all the rest put together and so we shall return to it in Chapter 11. Then in Chapter 15, after we’ve discussed a wider range of molecules, there will be a review chapter to bring the ideas together and show you how unknown structures are really determined.
you would like more details of any of the spectroscopic methods we discuss, you should refer to a specialized book.

**X-ray is the final appeal**

In Chapter 2 we suggested you draw saturated carbon chains as zig-zags and not in straight lines with 90° or 180° bond angles. This is because we know they are zig-zags. The X-ray crystal structure of the ‘straight’ chain diacid, hexanedioic acid, is shown below. You can clearly see the zig-zag chain the planar carboxylic acid groups, and even the hydrogen atoms coming towards you and going away from you. It obviously makes sense to draw this molecule realistically as in the second drawing.

\[
\text{HO}_2\text{C}-(\text{CH}_2)_4-\text{CO}_2\text{H}
\]

hexanedioic acid

shape of hexanedioic acid

data for structure taken from Cambridge Crystallographic Data Centre

This is one question that X-ray answers better than any other method: what shape does a molecule have? Another important problem it can solve is the structure of a new unknown compound. There are bacteria in oil wells, for example, that use methane as an energy source. It is amazing that bacteria manage to convert methane into anything useful, and, of course, chemists really wanted to know how they did it. Then in 1979 it was found that the bacteria use a coenzyme, given the trivial name ‘methoxatin’, to oxidize methane to methanol. Methoxatin was a new compound with an unknown structure and could be obtained in only very small amounts. It proved exceptionally difficult to solve the structure by NMR but eventually methoxatin was found by X-ray crystallography to be a polycyclic tricarboxylic acid. This is a more complex molecule than hexanedioic acid but X-ray crystallographers routinely solve much more complex structures than this.

**X-ray crystallography has its limitations**

If X-ray crystallography is so powerful, why do we bother with other methods? There are two reasons.

- X-ray crystallography works by the scattering of X-rays from electrons and requires crystalline solids. If an organic compound is a liquid or is a solid but does not form good crystals, its structure cannot be determined in this way.
X-ray crystallography is a science in its own right, a separate discipline from chemistry because it requires specific skills, and a structure determination can take a long time. Modern methods have reduced this time to a matter of hours or less, but nonetheless by contrast a modern NMR machine with a robot attachment can run more than 100 spectra in an overnight run. So we normally use NMR routinely and reserve X-rays for difficult unknown structures and for determining the detailed shape of important molecules.

Outline of structure determination by spectroscopy

Put yourself in these situations.

- Finding an unknown product from a chemical reaction
- Discovering an unknown compound from Nature
- Detecting a suspected food contaminant
- Routinely checking purity during the manufacture of a drug

In all cases except perhaps the second you need a quick and reliable answer. Suppose you are trying to identify the heart drug propranolol, one of the famous ‘beta blockers’ used to reduce high blood pressure and prevent heart attacks. You would first want to know the molecular weight and atomic composition and this would come from a mass spectrum: propranolol has a molecular weight (relative molecular mass) of 259 and the composition $C_{16}H_{21}NO_2$. Next you would need the carbon skeleton—this would come from NMR, which would reveal the three fragments shown.

There are many ways in which these fragments could be joined together and at this stage you would have no idea whether the oxygen atoms were present as OH groups or as ethers, whether the nitrogen would be an amine or not, and whether Y and Z might or might not be the same atom, say N. More information comes from the infrared spectrum, which highlights the functional groups, and which would show that there is an OH and an NH in the molecule but not functional groups such as CN or NO$_2$. This still leaves a variety of possible structures, and these could finally be distinguished by another technique, $^1$H NMR. We are in fact going to avoid using $^1$H NMR in this chapter, because it is more difficult, but you will learn just how much information can be gained from mass spectra, IR spectra, and $^{13}$C NMR spectra.

Now we must go through each of these methods and see how they give the information they do. For this exercise, we will use some compounds you encounter in everyday life, perhaps without realizing it.

[Note: This text contains chemical structures and diagrams that are not as easily interpreted in natural text format.]
Mass spectrometry

Mass spectrometry weighs the molecule

A mass spectrometer has three basic components: something to volatilize and ionize the molecule into a beam of charged particles; something to focus the beam so that particles of the same mass:charge ratio are separated from all others; and something to detect the particles. All spectrometers in common use operate in a high vacuum and usually use positive ions. Two methods are used to convert neutral molecules into cations: electron impact and chemical ionization.

Mass spectrometry by electron impact

In electron impact (E.I.) mass spectrometry the molecule is bombarded with highly energetic electrons that knock a weakly bound electron out of the molecule. If you think this is strange, think of throwing bricks at a brick wall: the bricks do not stick to the wall but knock loose bricks off the top of the wall. Losing a single electron leaves behind a radical cation: an unpaired electron and a positive charge. The electron that is lost will be one of relatively high energy (the bricks come from the top of the wall), and this will typically be one not involved in bonding, for example, an electron from a lone pair. Thus ammonia gives NH₃⁺ and a ketone gives R₂C=O⁺⁺. If the electron beam is not too high in energy, some of these rather unstable radical cations will survive the focusing operation and get to the detector. Normally two focusing operations are used: the beam is bent magnetically and electrostatically to accelerate the cations on their way to the detector and it takes about 20 μs for the cations to get there. But if, as is often the case, the electron beam supplies more than exactly the right amount of energy to knock out the electron, the excess energy is dissipated by fragmentation of the radical cation. Schematically, an unknown molecule first forms the radical cation M⁺⁺ which then breaks up (fragments) to give a radical X⁻ and a cation Y⁺. Only charged particles (cations in most machines) can be accelerated and focused by the magnetic and electrostatic fields and so the detector records only the molecular ion M⁺⁺ and positively charged fragments Y⁺. Uncharged radicals X⁻ are not recorded.

### What each spectroscopic method tells us

A typical result is the E.I. mass spectrum for the alarm pheromone of the honey bee. The bees check every insect coming into the hive for strangers. If a strange insect (even a bee from another hive) is detected, an alarm pheromone is released and the intruder is attacked. The pheromone is a simple volatile organic molecule having this mass spectrum.

The strongest peak, at 43 mass units in this case, is assigned an 'abundance' of 100% and called the base peak. The abundance of the other peaks is shown relative to the base peak. In this spectrum, there is only one other strong peak (58 at 50%) and the peak of highest mass at 114 (at 5%) is the molecular ion corresponding to a structure $C_7H_{14}O$. The main fragmentation is to a $C_5H_{11}{\cdot}$ radical (not observed as it isn’t charged) and a cation $C_2H_3O^+$, which forms the base peak. The pheromone is the simple ketone heptan-2-one.

The problem with E.I. is that for many radical cations even 20 $\mu$s is too long, and all the molecular ions have decomposed by the time they reach the detector. The fragments produced may be useful in identifying the molecule, but even in the case of the bee alarm pheromone it would obviously be better to get a stronger and more convincing molecular ion as the weak (5%) peak at 114 might also be a fragment or even an impurity.
Mass spectrometry by chemical ionization

In chemical ionization (C.I.) mass spectrometry the electron beam is used to ionize a simple molecule such as methane which in turn ionizes our molecule by collision and transfer of a proton. Under electron bombardment, methane loses a bonding electron (it doesn’t have any other kind) to give CH₄⁺ which reacts with a unionized methane molecule to give CH₃ and CH₅⁺. Before you write in complaining about a mistake, just consider that last structure in a bit more detail. Yes, CH₅⁺ does have a carbon atom with five bonds. But it has only eight electrons! These are distributed between five bonds (hence the + charge) and the structure is thought to be trigonal bipyramidal. This structure has not been determined as it is too unstable. It is merely proposed from theoretical calculations.

This unstable compound is a powerful acid, and can protonate just about any other molecule. When it protonates our sample, a proton has been added rather than an electron removed, so the resulting particles are simple cations, not radical cations, and are generally more stable than the radical cations produced by direct electron impact. So the molecular ion has a better chance of lasting the necessary 20 μs to reach the detector. Note that we now observe [M + H]⁺ (i.e. one more than the molecular mass) rather than M⁺ by this method.

Having more functional groups helps molecular ions to decompose. The aromatic amine 2-phenylethylamine is a brain active amine found in some foods such as chocolate, red wine, and cheese and possibly implicated in migraine. It gives a poor molecular ion by E.I., a base peak with a mass as low as 30 and the only peak at higher mass is a 15% peak at 91. The C.I. mass spectrum on the other hand has a good molecular ion: it is [M + H]⁺ of course. Normally a fragmentation gives one cation and another radical, only the cation being detected. It is relatively unusual for one bond to be able to fragment in either direction, but here it does, which means that both fragments are seen in the spectrum.

Mass spectrometry separates isotopes

You will know in theory that most elements naturally exist as mixtures of isotopes. If you didn’t believe it, now you will. Chlorine is normally a 3:1 mixture of ³⁵Cl and ³⁷Cl (hence the obviously false relative atomic mass of ‘35.5’ for chlorine) while bromine is an almost 1:1 mixture of ⁷⁹Br and ⁸¹Br (hence the ‘average’ mass of 80 for bromine!). Mass spectrometry separates these isotopes so that you get true not average molecular weights. The molecular ion in the E.I. mass spectrum of the bromo-amide below has two peaks at 213 and 215 of roughly equal intensity. This might just represent the loss of molecular hydrogen from a molecular ion 215, but, when we notice that the first fragment (and base peak) has the same pattern at 171/173, the presence of bromine is a more likely explanation. All the smaller fragments at 155, 92, etc. lack the 1:1 pattern and also therefore lack bromine.
The mass spectrum of chlorobenzene (PhCl, C₆H₅Cl) is very simple. There are two peaks at 112 (100%) and 114 (33%), a peak at 77 (40%), and very little else. The peaks at 112/114 with their 3:1 ratio are the molecular ions, while the fragment at 77 is the phenyl cation (Ph⁺ or C₆H₅⁺).

The mass spectrum of DDT is very revealing. This very effective insecticide became notorious as it accumulated in the fat of birds of prey (and humans) and was phased out of use. It can be detected easily by mass spectrometry because the five chlorine atoms produce a complex molecular ion at 252/254/256/258/260 with ratios of 243:405:270:90:15:1 (the last is too small to see). The peak at 252 contains nothing but ³⁵Cl, the peak at 254 has four atoms of ³⁵Cl and one atom of ³⁷Cl, while the invisible peak at 260 has five ³⁷Cl atoms. The ratios need some working out, but the first fragment at 235/237/239 in a ratio 9:6:1 is easier. It shows just two chlorine atoms as the CCl₃ group has been lost as a radical, leaving C₁₃H₆Cl₂⁺.

It’s worth remembering that the Ph⁺ weights 77: you’ll see this mass frequently.

Remember: mass spectroscopy is very good at detecting minute quantities.
Carbon has a minor but important isotope \(^{13}\text{C}\)

Many elements have minor isotopes at below the 1% level and we can ignore these. One important one we cannot ignore is the 1.1% of \(^{13}\text{C}\) present in ordinary carbon. The main isotope is \(^{12}\text{C}\) and you may recall that \(^{14}\text{C}\) is radioactive and used in carbon dating, but its natural abundance is minute. The stable isotope \(^{13}\text{C}\) is not radioactive, but it is NMR active as we shall soon see. If you look back at the mass spectra illustrated so far in this chapter, you will see a small peak one mass unit higher than each peak in most of the spectra. This is no instrumental aberration: these are genuine peaks containing \(^{13}\text{C}\) instead of \(^{12}\text{C}\). The exact height of these peaks is useful as an indication of the number of carbon atoms in the molecule. If there are \(n\) carbon atoms in a molecular ion, then the ratio of \(M^+\) to \([M + 1]^+\) is 100: \((1.1) \times n\).
The electron impact mass spectrum of BHT gives a good example. The molecular ion at 220 has an abundance of 34% and [M + 1]+ at 221 has 5–6% abundance but is difficult to measure as it is so weak. BHT is C15H26O so this should give an [M + 1]+ peak due to $^{13}\text{C}$ of 15 \times 1.1\% of M+, that is, 16.5\% of M+ or $34 \times 16.5 = 5.6\%$ actual abundance. An easier peak to interpret is the base peak at 205 formed by the loss of one of the six identical methyl groups from the $t$-butyl side chains (don’t forget what we told you in Chapter 2—all the ‘sticks’ in these structures are methyl groups and not hydrogen atoms). The base peak (100%) 205 is [M—Me]+ and the $^{13}\text{C}$ peak 206 is 15%, which fits well with $14 \times 1.1\% = 15.4\%$.

Other examples you have seen include the DDT spectrum, where the peaks between the main peaks are $^{13}\text{C}$ peaks: thus 236, 238, and 240 are each 14\% of the peak one mass unit less, as this fragment has 13 carbon atoms. If the number of carbons gets very large, so does the $^{13}\text{C}$ peak; eventually it is more likely that the molecule contains one $^{13}\text{C}$ than that it doesn’t. We can ignore the possibility of two $^{13}\text{C}$ atoms as 1.1\% of 1.1\% is very small (probability of $1.32 \times 10^{-5}$).

Table 3.2 summarizes the abundance of the isotopes in these three elements. Notice that the ratio for chlorine is not exactly 3:1 nor that for bromine exactly 1:1; nevertheless you should use the simpler ratios when examining a mass spectrum. Always look at the heaviest peak first: see whether there is chlorine or bromine in it,
and whether the ratio of $M^+$ to $[M + 1]^+$ is about right. If, for example, you have what seems to be $M^+$ at 120 and the peak at 121 is 20% of the supposed $M^+$ at 120, then this cannot be a $^{13}$C peak as it would mean that the molecule would have to contain 18 carbon atoms and you cannot fit 18 carbon atoms into a molecular ion of 120. Maybe 121 is the molecular ion.

**Atomic composition can be determined by high resolution mass spectrometry**

Ordinary mass spectra tell us the molecular weight (MW) of the molecule: we could say that the bee alarm pheromone was MW 114. When we said it was C$_7$H$_{14}$O we could not really speak with confidence because 114 could also be many other things such as C$_8$H$_{18}$ or C$_6$H$_{16}$O$_2$ or C$_6$H$_{14}$N$_2$. These different atomic compositions for the same molecular weight can nonetheless be distinguished if we know the exact molecular weight, since individual isotopes have non-integral masses (except $^{12}$C by definition). Table 3.3 gives these to five decimal places, which is the sort of accuracy you need for meaningful results. Such accurate mass measurements are called high resolution mass spectrometry.

For the bee alarm pheromone, the accurate mass turns out to be 114.1039. Table 3.4 compares possible atomic compositions, and the result is conclusive. The exact masses to three places of decimals fit the observed exact mass only for the composition C$_7$H$_{14}$O. You may not think the fit is very good when you look at the two numbers, but notice the difference in the error expressed as parts per million. One answer stands out from the rest. Note that even two places of decimals would be enough to distinguish these four compositions.

A more important case is that of the three ions at 28: nitrogen, carbon monoxide, and ethylene (ethene, CH$_2$=CH$_2$). Actually mass spectra rarely go down to this low value because some nitrogen is usually injected along with the sample, but the three ions are all significant and it is helpful to see how different they are. Carbon monoxide CO is 27.9949, nitrogen N$_2$ is 28.0061, and ethylene 28.0313.

One thing you may have noticed in Table 3.4 is that there are no entries with just one nitrogen atom. Two nitrogen atoms, yes; one nitrogen no! This is because any complete molecule with one nitrogen in it has an odd molecular weight. Look back at the mass spectrum of the compounds giving good molecular ions by C.I. for an example. The nitro compound had M = 127 and the amine M = 121. This is because C, O, and N all have even atomic weights—only H has an odd atomic weight. Nitrogen is the only element from C, O, and N that can form an odd number of bonds (3). Molecules with one nitrogen atom must have an odd number of hydrogen atoms and hence an odd molecular weight. Molecules with only C, H, and O or with even numbers of nitrogen atoms have even molecular weights.

If we are talking about fragments, that is, cations or radicals, the opposite applies. A fragment has, by definition, an unused valency. Look back at the fragments in this section and you will see that this is so. Fragments with C, H, O alone have odd molecular weights, while fragments with one nitrogen atom have even molecular weights.

**Nuclear magnetic resonance**

What does it do?

Nuclear magnetic resonance (NMR) allows us to detect atomic nuclei and say what sort of environment they are in, within their molecule. Clearly, the hydrogen of, say, propanol's hydroxyl group is...
different from the hydrogens of its carbon skeleton—it can be displaced by sodium metal, for example. NMR (actually $^1$H, or proton, NMR) can easily distinguish between these two sorts of hydrogens. Moreover, it can also distinguish between all the other different sorts of hydrogen atoms present. Likewise, carbon (or rather $^{13}$C) NMR can easily distinguish between the three different carbon atoms. In this chapter we shall look at $^{13}$C NMR spectra and then in Chapter 11 we shall look at proton ($^1$H) NMR spectra in detail.

NMR is incredibly versatile: it can even scan living human brains (see picture) but the principle is still the same: being able to detect nuclei (and hence atoms) in different environments. We need first to spend some time explaining the principles of NMR.

**NMR uses a strong magnetic field**

Imagine for a moment that we were able to ‘switch off’ the earth’s magnetic field. One effect would be to make navigation much harder since all compasses would be useless. They would be free to point in whatever direction they wanted to and, if we turned the needle round, it would simply stay where we left it. However, as soon as we switched the magnetic field back on, they would all point north—their lowest energy state. Now if we wanted to force a needle to point south we would have to use up energy and, of course, as soon as we let go, the needle would return to its lowest energy state, pointing north.

In a similar way, some atomic nuclei act like tiny compass needles and have different energy levels when placed in a magnetic field. The compass needle can rotate through 360° and have an essentially infinite number of different energy levels, all higher in energy than the ‘ground state’ (pointing north). Fortunately, our atomic nucleus is more restricted—its energy levels are quantized, just like the energy levels of an electron, which you will meet in the next chapter, and there are only certain specific energy levels it can adopt. This is like allowing our compass needle to point, say, only north or south. Some nuclei (including ‘normal’ carbon-12) do not interact with a magnetic field at all and cannot be observed in an NMR machine. The nuclei we shall be looking at, $^1$H and $^{13}$C, do interact and have just two different energy levels. When we apply a magnetic field to these nuclei, they can either align themselves with it, which would be the lowest energy state, or they can align themselves against the field, which is higher in energy.

Let us return to the compass for a moment. We have already seen that if we could switch off the earth’s magnetic field it would be easy to turn the compass needle round. When it is back on we need to push the needle (do work) to displace it from north. If we turned up the earth’s magnetic field still more, it would be even harder to displace the compass needle. Exactly how hard it is to turn the compass needle depends on how strong the earth’s magnetic field is and also on how well our needle is magnetized—if it is only weakly magnetized, it is much easier to turn it round and, if it isn’t magnetized at all, it is free to rotate.

Likewise, with our nucleus in a magnetic field, the difference in energy between the nuclear spin aligned with and against the applied field depends on how strong the magnetic field is, and also on the properties of the nucleus itself. The stronger the magnetic field we put our nucleus in, the greater the energy difference between the two alignments. Now here is an unfortunate thing about NMR: the energy difference between the nuclear spin being aligned with the magnetic field and against it is really very small—so small that we need a very, very strong magnetic field to see any difference at all.
NMR also uses radio waves

A $^1$H or $^{13}$C nucleus in a strong magnetic field can have two energy levels. We could do work to make our nucleus align against the field rather than with it (just like turning the compass needle round). But since the energy difference between the two states is so small, we don’t need to do much work. In fact, the amount of energy needed to flip the nucleus can be provided by electromagnetic radiation of radio-wave frequency. Radio waves flip the nucleus from the lower energy state to the higher state. The nucleus now wants to return to the lower energy state and, when it does so, the energy comes out again and this (a tiny pulse of radiofrequency electromagnetic radiation) is what we detect.

We can now sum up how an NMR machine works.

1. The sample of the unknown compound is dissolved in a suitable solvent and put in a very strong magnetic field. Any atomic nuclei with a nuclear spin now have different energy levels, the exact number of different energy levels depending on the value of the nuclear spin. For $^1$H and $^{13}$C NMR there are two energy levels

2. The sample is irradiated with a short pulse of radiofrequency energy. This disturbs the equilibrium balance between the two energy levels: some nuclei absorb the energy and are promoted to a higher energy level

3. We then detect the energy given out when the nuclei fall back down to the lower energy level using what is basically a sophisticated radio receiver

4. After lots of computation, the results are displayed in the form of intensity (i.e. number of absorptions) against frequency. Here is an example, which we shall return to in more detail later

Why do chemically distinct nuclei absorb energy at different frequencies?

In the spectrum you see above, each line represents a different kind of carbon atom: each one absorbs energy (or resonates—hence the term nuclear magnetic resonance) at a different frequency. But why should carbon atoms be ‘different’? We have told you two factors that affect the energy difference (and therefore the frequency)—the magnetic field strength and what sort of nucleus is being studied. So you might expect all carbon-13 nuclei to resonate at one particular frequency and all protons ($^1$H) to resonate at one (different) frequency. But they don’t.
The variation in frequency for different carbon atoms must mean that the energy jump from nucleus-aligned-with to nucleus-aligned-against the applied magnetic field must be different for each type of carbon atom. The reason there are different types of carbon atom is that their nuclei experience a magnetic field that is not quite the same as the magnetic field that we apply. Each nucleus is surrounded by electrons, and in a magnetic field these will set up a tiny electric current. This current will set up its own magnetic field (rather like the magnetic field set up by the electrons of an electric current moving through a coil of wire or solenoid), which will oppose the magnetic field that we apply. The electrons are said to shield the nucleus from the external magnetic field. If the electron distribution varies from $^{13}$C atom to $^{13}$C atom, so does the local magnetic field, and so does the resonating frequency of the $^{13}$C nuclei. Now, you will see shortly (in Chapter 5) that a change in electron density at a carbon atom also alters the chemistry of that carbon atom. NMR tells us about the chemistry of a molecule as well as about its structure.

As an example, consider ethanol, CH$_3$CH$_2$OH. The carbon attached to the OH group will have relatively fewer electrons around it compared to the other carbon since the oxygen atom is more electronegative and draws electrons towards it, away from the carbon atom.

The magnetic field that this (red) carbon nucleus feels will therefore be slightly greater than that felt by the (green) carbon with more electrons since the red carbon is less shielded from the applied external magnetic field—in other words it is deshielded. Since the carbon attached to the oxygen feels a stronger magnetic field, there will be a greater energy difference between the two alignments of its nucleus. The greater the energy difference, the higher the resonant frequency. So for ethanol we would expect the red carbon with the OH group attached to resonate at a higher frequency than the green carbon, and indeed this is exactly what the $^{13}$C NMR spectrum shows.

The chemical shift scale
When you look at an NMR spectrum you will see that the scale does not appear to be in magnetic field units, nor in frequency units, but in ‘parts per million’ (p.p.m.). There is an excellent reason for
this and we need to explain it. The exact frequency at which the nucleus resonates depends on the external applied magnetic field. This means that, if the sample is run on a machine with a different magnetic field, it will resonate at a different frequency. It would make life very difficult if we couldn’t say exactly where our signal was, so we say how far it is from some reference sample, as a fraction of the operating frequency of the machine. We know that all protons resonate at approximately the same frequency in a given magnetic field and that the exact frequency depends on what sort of chemical environment it is in, which in turn depends on its electrons. This approximate frequency is the operating frequency of the machine and simply depends on the strength of the magnet—the stronger the magnet, the larger the operating frequency. The precise value of the operating frequency is simply the frequency at which a standard reference sample resonates. In everyday use, rather than actually referring to the strength of the magnet in tesla, chemists usually just refer to its operating frequency. A 9.4 T NMR machine is referred to as a 400 MHz spectrometer since that is the frequency in this strength field at which the protons in the reference sample resonate; other nuclei, for example $^{13}\text{C}$, would resonate at a different frequency, but the strength is arbitrarily quoted in terms of the proton operating frequency.

**The reference sample—tetramethylsilane, TMS**

The compound we use as a reference sample is usually tetramethylsilane, TMS. This is silane ($\text{SiH}_4$) with each of the hydrogen atoms replaced by methyl groups to give $\text{Si(CH}_3)_4$. The four carbon atoms attached to silicon are all equivalent and, because silicon is more electronegative than carbon, are fairly electron-rich (or shielded), which means they resonate at a frequency a little less than that of most organic compounds. This is useful because it means our reference sample is not bang in the middle of our spectrum!

The chemical shift, $\delta$, in parts per million (p.p.m.) of a given nucleus in our sample is defined in terms of the resonance frequency as:

$$\delta = \frac{\text{frequency (Hz)} - \text{frequency TMS (Hz)}}{\text{frequency TMS (MHz)}}$$

No matter what the operating frequency (i.e. strength of the magnet) of the NMR machine, the signals in a given sample (e.g. ethanol) will always occur at the same chemical shifts. In ethanol the (red) carbon attached to the OH resonates at 57.8 p.p.m. whilst the (green) carbon of the methyl group resonates at 18.2 p.p.m. Notice that by definition TMS itself resonates at 0 p.p.m. The carbon nuclei in most organic compounds resonate at greater chemical shifts, normally between 0 and 200 p.p.m.

Now, let’s return to the sample spectrum you saw on p. 000 and which is reproduced below, and you can see the features we have discussed. This is a 100 MHz spectrum; the horizontal axis is actually frequency but is usually quoted in p.p.m. of the field of the magnet, so each unit is one p.p.m. of 100 MHz, that is, 100 Hz. We can tell immediately from the three peaks at 176.8, 66.0, and 19.9 p.p.m. that there are three different types of carbon atom in the molecule.

But we can do better than this: we can also work out what sort of chemical environment the carbon atoms are in. All $^{13}\text{C}$ spectra can be divided into four major regions: saturated carbon atoms (0–50 p.p.m.), saturated carbon atoms next to oxygen (50–100 p.p.m.), unsaturated carbon atoms (100–150 p.p.m.), and unsaturated carbon atoms next to oxygen, i.e. $\text{C}=\text{O}$ groups (150–200 p.p.m.).
The spectrum you just saw is in fact of lactic acid (2-hydroxypropanoic acid). When you turned the last page, you made some lactic acid from glucose in the muscles of your arm—it is the breakdown product from glucose when you do anaerobic exercise. Each of lactic acid’s carbon atoms gives a peak in a different region of the spectrum.

Different ways of describing chemical shift

The chemical shift scale runs to the left from zero (where TMS resonates)—i.e. backwards from the usual style. Chemical shift values around zero are obviously small but are confusingly called ‘high field’ because this is the high magnetic field end of the scale. We suggest you say ‘large’ or ‘small’ chemical shift and ‘large’ or ‘small’ δ, but ‘high’ or ‘low’ field to avoid confusion. Alternatively, use ‘upfield’ for high field (small δ) and ‘downfield’ for low field (large δ).

One helpful description we have already used is shielding. Each carbon nucleus is surrounded by electrons that shield the nucleus from the applied field. Simple saturated carbon nuclei are the most shielded: they have small chemical shifts (0–50 p.p.m.) and resonate at high field. One electron-negative oxygen atom moves the chemical shift downfield into the 50–100 p.p.m. region. The nucleus has become deshielded. Unsaturated carbon atoms experience even less shielding (100–150 p.p.m.) because of the way in which electrons are distributed around the nucleus. If the π bond is to oxygen, then the nucleus is even more deshielded and moves to the largest chemical shifts around 200 p.p.m. The next diagram summarizes these different ways of talking about NMR spectra.

A guided tour of NMR spectra of simple molecules

We shall first look at NMR spectra of a few simple compounds before looking at unknown structures. Our very first compound, hexanedioic acid, has the simple NMR spectrum shown here. The first question is: why only three peaks for six carbon atoms? Because of the symmetry of the molecule, the two carboxylic acids are identical and give one peak at 174.2 p.p.m. By the same token C2 and C5 are identical while C3 and C4 are identical. These are all in the saturated region 0–50 p.p.m. but it is likely that the carbons next to the electron-withdrawing CO₂H group are more deshielded than the others. So we assign C2/C5 to the peak at 33.2 p.p.m. and C3/C4 to 24.0 p.p.m.
The bee alarm pheromone (heptan-2-one) has no symmetry so all its seven carbon atoms are different. The carbonyl group is easy to identify (208.8 p.p.m., highlighted in red) but the rest are more difficult. Probably the two carbon atoms next to the carbonyl group come at lowest field, while C7 is certainly at highest field (13.9 p.p.m.). It is important that there are the right number of signals at about the right chemical shift. If that is so, we are not worried if we cannot assign each frequency to a precise carbon atom.

You met BHT on p. 000: its formula is C15H24O and the first surprise in its NMR spectrum is that there are only seven signals for the 15 carbon atoms. There is obviously a lot of symmetry; in fact the molecule has a plane of symmetry vertically as it is drawn here. The very strong signal at $\delta = 30.4$ p.p.m. belongs to the six identical methyl groups on the t-butyl groups and the other two signals in the 0–50 p.p.m. range are the methyl group at C4 and the central carbons of the t-butyl groups. In the aromatic region there are only four signals as the two halves of the molecule are the same. As with the last example, we are not concerned with exactly which is which; we just check that there are the right number of signals with the right chemical shifts.

Paracetamol is a familiar painkiller with a simple structure—it too is a phenol but in addition it has an amide on the benzene ring. Its NMR spectrum contains one saturated carbon atom at 24 p.p.m. (the methyl group of the amide side chain), one carbonyl group at 168 p.p.m., and four other peaks at 115, 122, 132, and 153 p.p.m. These are the carbons of the benzene ring. Why four peaks? The two sides of the benzene ring are the same because the NHCO-CH3 side chain can rotate rapidly so that C2 and C6 are the same and C3 and C5 are the same. Why is one of these aromatic peaks in the C=O region at 153 p.p.m.? This must be C4 as it is bonded to oxygen, and it just reminds us that carbonyl groups are not the only unsaturated carbon atoms bonded to oxygen (see the chart on p. 000), though it is not as deshielded as the true C=O group at 168 p.p.m.
The effects of deshielding within the saturated carbon region

We have mentioned deshielding several times. The reference compound TMS (Me₄Si) has very shielded carbon atoms because silicon is more electropositive than carbon. Oxygen moves a saturated carbon atom downfield to larger chemical shifts (50–100 p.p.m.) because it is much more electronegative than carbon and so pulls electrons away from a carbon atom by polarizing the C–O bond. In between these extremes was a CO₂H group that moved its adjacent carbon down to around 35 p.p.m. These variations in chemical shift within each of the 50 p.p.m. regions of the spectrum are a helpful guide to structure as the principle is simple.

- **Electronegative atoms move adjacent carbon atoms downfield (to larger δ) by deshielding.**

For the carbon atom next to the carboxylic acid, the oxygen atoms are, of course, no longer adjacent but one atom further away, so their deshielding effect is not as great.

The reverse is true too: electropositive atoms move adjacent carbon atoms upfield by shielding. This is not so important as there are few atoms found in organic molecules that are more electropositive than silicon and so few carbons are more shielded than those in Me₄Si. About the only important elements like this are the metals. When a carbon atom is more shielded than those in TMS, it has a negative δ value. There is nothing odd about this—the zero on the NMR scale is an arbitrary point. Table 3.5 shows a selection of chemical shift changes caused to a methyl group by changes in electronegativity.

The last column in Table 3.5 shows the effect that each substituent has when compared to ethane. In ethane there is no electronic effect because the substituent is another methyl group so this column gives an idea of the true shift caused by a substituent. These shifts are roughly additive. Look back at the spectrum of lactic acid on p. 000: the saturated carbons occur at 19.9 and 66.0. The one at 66.0 is next both to an oxygen atom and a carbonyl group so that the combined effect would be about 42 + 22 = 64—not a bad estimate.

**NMR is a powerful tool for solving unknown structures**

Simple compounds can be quickly distinguished by NMR. These three alcohols of formula C₄H₁₀O have quite different NMR spectra.
Each alcohol has a saturated carbon atom next to oxygen, all close together. Then there are carbons next door but one to oxygen: they are back in the 0–50 p.p.m. region but at its low field end—about 30–35 p.p.m.. Notice the similarity of these chemical shifts to those of carbons next to a carbonyl group (Table 3.5 on p. 000). In each case we have C–C–O and the effects are about the same. Two of the alcohols have carbon(s) one further away still at yet smaller chemical shift (further upfield, more shielded) at about 20 p.p.m., but only the \( n \)-butanol has a more remote carbon still at 15.2. The number and the chemical shift of the signals identify the molecules very clearly.

A more realistic example would be an unknown molecule of formula C\(_3\)H\(_6\)O. There are seven reasonable structures, as shown. Simple symmetry can distinguish structures A, C, and E from the rest as these three have only two types of carbon atom. A more detailed inspection of the spectra makes identification easy. The two carbonyl compounds, D and E, each have one peak in the 150–220 p.p.m. region but D has two different saturated carbon atoms while E has only one. The two alkenes, F and G, both have one saturated carbon atom next to oxygen, but F has two normal unsaturated carbon atoms (100–150 p.p.m.) while the enol ether, G, has one normal alkene and one unsaturated carbon joined to oxygen. The three saturated compounds (A–C) present the greatest problem. The epoxide, B, has two different carbon atoms next to oxygen (50–100 p.p.m.) and one normal saturated carbon atom. The remaining two both have one signal in the 0–50 and one in the 50–100 p.p.m. regions. Only proton NMR (Chapter 11) and, to a certain extent, infrared spectroscopy (which we will move on to shortly) will distinguish them reliably.

Here are NMR spectra of three of these molecules. Before looking at the solutions, cover up the rest of the page and see if you can assign them to the structures above. Try also to suggest which signals belong to which carbon atoms.

The C atoms have been arbitrarily colour-coded.

The meanings of \( n \), iso-, and \( t \) were covered in Chapter 2 (p. 000).

An epoxide is a three-membered cyclic ether.
These shouldn’t give you too much trouble. The only carbonyl compound with two identical carbons is acetone, $\text{Me}_2\text{CO}$ (E) so spectrum 3 must be that one. Notice the very low field C=O signal (206.6 p.p.m.) typical of a simple ketone. Spectrum 1 has two unsaturated carbons and a saturated carbon next to oxygen so it must be F or G. In fact it has to be F as both unsaturated carbons are similar (137 and 116 p.p.m.) and neither is next to oxygen (>150 p.p.m., cf. 206.6 in spectrum 3). This leaves spectrum 2, which appears to have no carbon atoms next to oxygen as all chemical shifts are less than 50 p.p.m. No compound fits that description (impossible for $\text{C}_3\text{H}_6\text{O}$ anyway!) and the two signals at 48.0 and 48.2 p.p.m. are suspiciously close to the borderline. They are, of course, next to oxygen and this is compound B.

Infrared spectra

Functional groups are identified by infrared spectra

Some functional groups, for example, C=O or C=C, can be seen in the NMR spectrum because they contain carbon atoms, while the presence of others like OH can be inferred from the chemical shifts of the carbon atoms they are joined to. Others cannot be seen at all. These might include NH$_2$ and NO$_2$, as well as variations around a carbonyl group such as COCl, CO$_2$H, and CONH$_2$. Infrared (IR) spectroscopy provides a way of finding these functional groups because it detects the stretching and bending of bonds rather than any property of the atoms themselves. It is particularly good at detecting the stretching of unsymmetrical bonds of the kind found in functional groups such as OH, C=O, NH$_2$, and NO$_2$.

NMR requires electromagnetic waves in the radio-wave region of the spectrum to make nuclei flip from one state to another. The amount of energy needed for stretching and bending individual bonds, while still very small, corresponds to rather shorter wavelengths. These wavelengths lie in the infrared, that is, heat radiation just to the long wavelength side of visible light. When the carbon skeleton of a molecule vibrates, all the bonds stretch and relax in combination and these absorptions are unhelpful. However some bonds stretch essentially independently of the rest of the molecule. This occurs if the bond is either:

- much stronger or weaker than others nearby, or
- between atoms that are much heavier or lighter than their neighbours

Indeed, the relationship between the frequency of the bond vibration, the mass of the atoms, and the strength of the bond is essentially the same as Hooke’s law for a simple harmonic oscillator.

$$\nu = \frac{1}{2\pi} \sqrt{\frac{f}{\mu}}$$

The equation shows that the frequency of the vibration $\nu$ is proportional to the (root of) a force constant $f$—more or less the bond strength—and inversely proportional to the (root of) a reduced mass $\mu$, that is, the product of the masses of the two atoms forming the bond divided by their sum.

$$\mu = \frac{m_1 m_2}{m_1 + m_2}$$

Stronger bonds vibrate faster and so do lighter atoms. You may at first think that stronger bonds ought to vibrate more slowly, but a moment’s reflection will convince you of the truth: which stretches and contracts faster, a tight steel spring or a slack steel spring?

Infrared spectra are simple absorption spectra. The sample is exposed to infrared radiation and the wavelength scanned across the spectrum. Whenever energy corresponding to a specific wavelength is absorbed, the intensity of the radiation reaching a detector momentarily decreases, and this is recorded in the spectrum. Infrared spectra are usually recorded using a frequency measurement called wavenumber ($\text{cm}^{-1}$) which is the inverse of the true wavelength $\lambda$ in centimetres to give convenient numbers (500–4000 cm$^{-1}$). Higher numbers are to the left of the spectrum because it is really wavelength that is being scanned.
We need to use another equation here:

\[ E = h\nu = h\frac{c}{\lambda} \quad \text{since} \quad \lambda = \frac{c}{\nu} \]

The energy, \( E \), required to excite a bond vibration can be expressed as the inverse of a wavelength \( \lambda \) or as a frequency \( \nu \). Wavelength and frequency are just two ways of measuring the same thing. More energy is needed to stretch a strong bond and you can see from this equation that larger \( E \) means higher wavenumbers (cm\(^{-1}\)) or smaller wavelength (cm).

To run the spectrum, the sample is either dissolved in a solvent such as CHCl\(_3\) (chloroform) that has few IR absorptions, pressed into a transparent disc with powdered solid KBr, or ground into an oily slurry called a mull with a hydrocarbon oil called ‘Nujol’. Solutions in CHCl\(_3\) cannot be used for looking at the regions of C–Cl bond stretching nor can Nujol mulls be used for the region of C–H stretching. Neither of these is a great disadvantage, especially as nearly all organic compounds have some C–H bonds anyway.

We shall now examine the relationship between bond stretching and frequency in more detail. Hooke’s law told us to expect frequency to depend on both mass and bond strengths, and we can illustrate this double dependence with a series of bonds of various elements to carbon.

| Values chiefly affected by mass of atoms: (lighter atom, higher frequency) |
|-----------------|----------------|----------------|----------------|
| C–H             | C–D            | C–O            | C–Cl           |
| 3000 cm\(^{-1}\) | 2200 cm\(^{-1}\) | 1100 cm\(^{-1}\) | 700 cm\(^{-1}\) |

| Values chiefly affected by bond strength (stronger bond, higher frequency) |
|----------------|----------------|----------------|
| C\(=\)O        | C=O            | C–O            |
| 2143 cm\(^{-1}\) | 1715 cm\(^{-1}\) | 1100 cm\(^{-1}\) |

Just because they were first recorded in this way, infrared spectra have the baseline at the top and peaks going downwards. You might say that they are plotted upside down and back to front. At least you are now accustomed to the horizontal scale running backwards as that happens in NMR spectra too. A new feature is the change in scale at 2000 cm\(^{-1}\) so that the right-hand half of the spectrum is more detailed than the left-hand half. A typical spectrum looks like this.
There are four important regions of the infrared spectrum

You will see at once that the infrared spectrum contains many lines, particularly at the right-hand (lower frequency) end; hence the larger scale at this end. Many of these lines result from several bonds vibrating together and it is actually the left-hand half of the spectrum that is more useful.

The first region, from about 4000 to about 2500 cm\(^{-1}\) is the region for C–H, N–H, and O–H bond stretching. Most of the atoms in an organic molecule (C, N, O, for example) are about the same weight. Hydrogen is an order of magnitude lighter than any of these and so it dominates the stretching frequency by the large effect it has on the reduced mass. The reduced mass of a C–C bond is \((12 \times 12)/(12 + 12)\), i.e. 144/24 = 6.0. If we change one of these atoms for H, the reduced mass changes to \((12 \times 1)/ (12 + 1)\), i.e. 12/13 = 0.92, but, if we change it instead for F, the reduced mass changes to \((12 \times 19)/ (12 + 19)\), i.e. 228/31 = 7.35. There is a small change when we increase the mass to 19 (F), but an enormous change when we decrease it to 1 (H).

Even the strongest bonds—triple bonds such as C≡C or C≡N—absorb at slightly lower frequencies than bonds to hydrogen: these are in the next region from about 2500 to 2000 cm\(^{-1}\). This and the other two regions of the spectrum follow in logical order of bond strength as the reduced masses are all about the same: double bonds such as C=C and C=O from about 1900–1500 cm\(^{-1}\) and single bonds at the right-hand end of the spectrum. These regions are summarized in this chart, which you should memorize.

Looking back at the typical spectrum, we see peaks in the X–H region at about 2950 cm\(^{-1}\) which are the C–H stretches of the CH\(_3\) and CH\(_2\) groups. The one rather weak peak in the triple bond region (2270 cm\(^{-1}\)) is of course the C≡N group and the strong peak at about 1670 cm\(^{-1}\) belongs to the C=O group. We shall explain soon why some IR peaks are stronger than others. The rest of the spectrum is in the single bond region. This region is not normally interpreted in detail but is characteristic of the compound as a whole rather in the way that a fingerprint is characteristic of an individual human...
being—and, similarly, it cannot be ‘interpreted’. It is indeed called the fingerprint region. The useful information from this spectrum is the presence of the CN and C=O groups and the exact position of the C=O absorption.

The X–H region distinguishes C–H, N–H, and O–H bonds

The reduced masses of the C–H, N–H, and O–H combinations are all about the same. Any difference between the positions of the IR bands of these bonds must then be due to bond strength. In practice, C–H stretches occur at around 3000 cm\(^{-1}\) (though they are of little use as virtually all organic compounds have C–H bonds), N–H stretches occur at about 3300 cm\(^{-1}\), and O–H stretches higher still. We can immediately deduce that the O–H bond is stronger than N–H which is stronger than C–H. IR is a good way to measure such bond strengths.

\(^a\)When not hydrogen-bonded: see below.

The X–H IR stretches are very different in these four compounds.

The IR peak of an NH group is different from that of an NH\(_2\) group. A group gives an independent vibration only if both bond strength and reduced mass are different from those of neighbouring bonds. In the case of N–H, this is likely to be true and we usually get a sharp peak at about 3300 cm\(^{-1}\), whether the NH group is part of a simple amine (R\(_2\)NH) or an amide (RCONHR). The NH\(_2\) group is also independent of the rest of the molecule, but the two NH bonds inside the NH\(_2\) group have identical force constants and reduced masses and so vibrate as a single unit. Two equally strong bands appear, one for the two N–H bonds vibrating in phase (symmetric) and one for the two N–H bonds vibrating in opposition (antisymmetric). The antisymmetric vibration requires more energy and is at slightly higher frequency.
The O–H bands occur at higher frequency, sometimes as a sharp absorption at about 3600 cm\(^{-1}\). More often, you will see a broad absorption at anywhere from 3500 to 2900 cm\(^{-1}\). This is because OH groups form strong hydrogen bonds that vary in length and strength. The sharp absorption at 3600 cm\(^{-1}\) is the non-hydrogen-bonded OH and the lower the absorption the stronger the H bond.

Alcohols form hydrogen bonds between the hydroxyl oxygen of one molecule and the hydroxyl hydrogen of another. These bonds are variable in length (though they are usually rather longer than normal covalent O–H bonds) and they slightly weaken the true covalent O–H bonds by varying amounts. When a bond varies in length and strength it will have a range of stretching frequencies distributed about a mean value. Alcohols typically give a rounded absorption at about 3300 cm\(^{-1}\) (contrast the sharp N–H stretch in the same region). Carboxylic acids (RCO2H) form hydrogen-bonded dimers with two strong H bonds between the carbonyl oxygen atom of one molecule and the acidic hydrogen of the other. These also vary considerably in length and strength and usually give very broad V-shaped absorbances.

Good examples are paracetamol and BHT. Paracetamol has a typical sharp peak at 3330 cm\(^{-1}\) for the N–H stretch and then a rounded absorption for the hydrogen-bonded O–H stretch from 3300 down to 3000 cm\(^{-1}\) in the gap between the N–H and C–H stretches. By contrast, BHT has a sharp absorption at 3600 cm\(^{-1}\) as the two large and roughly spherical t-butyl groups prevent the normal H bond from forming.
You may be confused the first time you see the IR spectrum of a terminal alkyne, \( R-\text{C} \equiv \text{C}-\text{H} \), because you will see a strongish sharp peak at around \( 3300 \text{ cm}^{-1} \) that looks just like an \( \text{N}–\text{H} \) stretch. The displacement of this peak from the usual \( \text{C}–\text{H} \) stretch at about \( 3000 \text{ cm}^{-1} \) cannot be due to a change in the reduced mass and must be due to a marked increase in bond strength. The alkyne \( \text{C}–\text{H} \) bond is shorter and stronger than alkane \( \text{C}–\text{H} \) bonds.

The double bond region is the most important in IR spectra

In the double bond region, there are three important absorptions, those of the carbonyl (\( \text{C}=\text{O} \)), alkene (\( \text{C}==\text{C} \)), and nitro (\( \text{NO}_2 \)) groups. All give rise to sharp bands: \( \text{C}=\text{O} \) to one strong (i.e. intense) band anywhere between 1900 and 1500 cm\(^{-1}\); \( \text{C}==\text{C} \) to one weak band at about 1640 cm\(^{-1}\); and \( \text{NO}_2 \) to two strong (intense) bands in the mid-1500s and mid-1300s cm\(^{-1}\). The number of bands is easily dealt with. Just as with \( \text{OH} \) and \( \text{NH}_2 \), it is a matter of how many identical bonds are present in the same functional group. Carbonyl and alkene clearly have one double bond each. The nitro group at first appears to contain two different groups, \( \text{N}^+–\text{O}^- \) and \( \text{N}=\text{O} \), but delocalization means they are identical and we see absorption for symmetrical and antisymmetrical stretching vibrations. As with \( \text{NH}_2 \), more work is needed for the antisymmetrical vibration which occurs at higher frequency (>1500 plus cm\(^{-1}\)).
The strength of an IR absorption depends on dipole moment

Now what about the variation in strength (i.e. intensity, the amount of energy absorbed)? The strength of an IR absorption varies with the change of dipole moment when the bond is stretched. If the bond is perfectly symmetrical, there is no change in dipole moment and there is no IR absorption. Obviously, the C=C bond is less polar than either C=O or N=O and is weaker in the IR. Indeed it may be absent altogether in a symmetrical alkene. By contrast the carbonyl group is very polar (Chapter 4) and stretching it causes a large change in dipole moment and C=O stretches are usually the strongest peaks in the IR spectrum. You may also have noticed that O–H and N–H stretches are stronger than C–H stretches (even though most organic molecules have many more C–H bonds than O–H or N–H bonds); the reason is the same.

Dipole moments

Dipole moment depends on the variation in distribution of electrons along the bond, and also its length, which is why stretching a bond can change its dipole moment. For bonds between unlike atoms, the larger the difference in electronegativity, the greater the dipole moment, and the more it changes when stretched. For identical atoms (C=C, for example) the dipole moment, and its capacity to change with stretching, is much smaller. Stretching frequencies for symmetrical molecules are measured using Raman spectra. This is an IR-based technique using scattered light that relies on polarizability of bonds. Raman spectra are outside the scope of this book.

This is a good point to remind you of the various deductions we have made so far about IR spectra.

Absorptions in IR spectra

| Strength of band depends on → | change in dipole moment | large dipole moment gives strong absorption |

| Width of band depends on → | hydrogen bonding | strong H bond gives wide peak |

We have seen three carbonyl compounds so far in this chapter and they all show peaks in the right region (around 1700 cm⁻¹) even though one is a carboxylic acid, one a ketone, and one an amide. We shall consider the exact positions of the various carbonyl absorptions in Chapter 15 after we have discussed some carbonyl chemistry.
The single bond region is used as a molecular fingerprint

The region below 1500 cm\(^{-1}\) is where the single bond vibrations occur. Here our hope that individual bonds may vibrate independently of the rest of the molecule is usually doomed to disappointment. The atoms C, N, and O all have about the same atomic weight and C–C, C–N, and C–O single bonds all have about the same strength.

In addition, C–C bonds are likely to be joined to other C–C bonds with virtually identical strength and reduced mass, and they have essentially no dipole moments. The only one of these single bonds of any value is C–O which is polar enough and different enough (Table 3.7) to show up as a strong absorption at about 1100 cm\(^{-1}\). Some other single bonds such as C–Cl (weak and with a large reduced mass) are quite useful at about 700 cm\(^{-1}\). Otherwise the single bond region is usually crowded with hundreds of absorptions from vibrations of all kinds used as a ‘fingerprint’ characteristic of the molecule but not really open to interpretation.

Among the hundreds of peaks in the fingerprint region, there are some of a quite different kind. Stretching is not the only bond movement that leads to IR absorption. Bending of bonds, particularly C–H and N–H bonds, also leads to quite strong peaks. These are called deformations. Bending a bond is easier than stretching it (which is easier, stretching or bending an iron bar?). Consequently, bending absorptions need less energy and come at lower frequencies than stretching absorptions for the same bonds. These bands may not often be useful in identifying molecules, but you will notice them as they are often strong (they are usually stronger than C=C stretches for example) and may wonder what they are.

Finally in this section, we summarize all the useful absorptions in the fingerprint region. Please be cautious in applying these as there are other reasons for bands in these positions.

Mass spectra, NMR, and IR combined make quick identification possible

If these methods are each as powerful as we have seen on their own, how much more effective they must be together. We shall finish this chapter with the identification of some simple unknown
compounds using all three methods. The first is an industrial emulsifier used to blend solids and liquids into smooth pastes. Its electron impact mass spectrum has peaks at 75 and 74 (each about 20%) and a base peak at 58. The two peaks at 75 and 74 cannot be isotopes of bromine as the separation is only one mass unit, nor can 75 be a $^{13}\text{C}$ peak as it is far too strong. It looks as though 75 might be the molecular ion and 74 an unusual loss of a hydrogen atom. However a chemical ionization mass spectrum reveals a molecular ion at 90 (MH$^+$) and hence the true molecular ion at 89. An odd molecular weight (89) suggests one nitrogen atom, and high resolution mass spectrometry reveals that the formula is C$_4$H$_{11}$NO.

The $^{13}\text{C}$ NMR spectrum has only three peaks so two carbon atoms must be the same. There is one signal for saturated carbon next to oxygen, and two for other saturated carbons, one more downfield than the other. The IR spectrum reveals a broad peak for an OH group with two sharp NH$_2$ peaks just protruding. If we put this together, we know we have C–OH and C–NH$_2$. Neither of these carbons can be duplicated (as there is only one O and only one N!) so one of the remaining carbons must be duplicated.
The next stage is one often overlooked. We don’t seem to have much information, but try and put the two fragments together, knowing the molecular formula, and there’s very little choice. The carbon chain (shown in red) could either be linear or branched and that’s it!

linear carbon chain

branched carbon chain

There is no room for double bonds or rings because we need to fit in the eleven hydrogen atoms. We cannot put N or O in the chain because we know from the IR that we have the chain terminating groups OH and NH₂. Of the seven possibilities only the last two, A and B, are serious since they alone have two identical carbon atoms (the two methyl groups in each case); all the other structures would have four separate signals in the NMR. How can we choose between these? The base peak in the mass spectrum was at 58 and this fits well with a fragmentation of one structure but not of the other: the wrong structure would give a fragment at 59 and not 58. The industrial emulsifier is 2-amino-2-methylpropan-1-ol.

Double bond equivalents help in the search for a structure

The last example was fully saturated but it is usually a help in deducing the structure of an unknown compound if, once you know the atomic composition, you immediately work out how much unsaturation there is. This is usually expressed as ‘double bond equivalents’. It may seem obvious to you that, if C₄H₁₁NO has no double bonds, then C₄H₇NO (losing two hydrogen atoms) must have one double bond, C₄H₉NO two double bonds, and so on. Well, it’s not quite as simple as that. Some possible structures for these formulae are shown below.

some structures for C₄H₇NO

some structures for C₄H₉NO
Some of these structures have the right number of double bonds (C=C and C=O), one has a triple bond, and three compounds use rings as an alternative way of ‘losing’ some hydrogen atoms. Each time you make a ring or a double bond, you have to lose two more hydrogen atoms. So double bonds (of all kinds) and rings are called **Double Bond Equivalents (DBEs)**.

You can work out how many DBEs there are in a given atomic composition just by making a drawing of one possible structure (all possible structures have the same number of DBEs). Alternatively, you can calculate the DBEs if you wish. A saturated hydrocarbon with \( n \) carbon atoms has \((2n + 2)\) hydrogens. Oxygen doesn’t make any difference to this: there are the same number of Hs in a saturated ether or alcohol as in a saturated hydrocarbon.

So, for a compound containing C, H, and O only, take the actual number of hydrogen atoms away from \((2n + 2)\) and divide by two. Just to check that it works, for the unsaturated ketone \( C_7H_{12}O \) the calculation becomes:

1. Maximum number of H atoms for 7 Cs \( 2n + 2 = 16 \)
2. Subtract the actual number of H atoms (12) \( 16 – 12 = 4 \)
3. Divide by 2 to give the DBEs \( 4/2 = 2 \)

C\(_7\)H\(_{12}\)O = two DBE

The unsaturated ketone does indeed have an alkene and a carbonyl group. The unsaturated cyclic acid has: \( 16 – 10 = 6 \) divided by \( 2 = 3 \) DBEs and it has one alkene, one C=O and one ring. Correct. The aromatic ether has \( 16 – 8 = 8 \) divided by \( 2 \) gives 4 DBEs and it has three double bonds in the ring and the ring itself. Correct again.

Nitrogen makes a difference. Every nitrogen adds one extra hydrogen atom because nitrogen can make three bonds. This is one fewer hydrogen to subtract. The formula becomes: subtract actual number of hydrogens from \((2n + 2)\), add one for each nitrogen atom, and divide by two. We can try this out too.

<table>
<thead>
<tr>
<th>1. Maximum number of H atoms for 7 Cs</th>
<th>( 2n + 2 = 16 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>2. Subtract the actual number of H atoms (12)</td>
<td>( 16 – 12 = 4 )</td>
</tr>
<tr>
<td>3. Divide by 2 to give the DBEs</td>
<td>( 4/2 = 2 )</td>
</tr>
</tbody>
</table>

C\(_7\)H\(_{12}\)O = two DBE

The saturated compound has \((2n + 3)\) Hs instead of \((2n + 2)\). The saturated nitro compound has \((2n + 2) = 16\) less 15 (the actual number of Hs) plus one (the number of nitrogen atoms) = 2. Divide this by \( 2 \) and you get 1 DBE, which is the N=O bond. The last compound (we shall meet this later as ‘DMAP’) has:

1. Maximum number of H atoms for 7 Cs \( 2n + 2 = 16 \)
2. Subtract the actual number of H atoms (10) \( 16 – 10 = 6 \)
3. Add number of nitrogens \( 6 + 2 = 8 \)
4. Divide by 2 to give the DBEs \( 8/2 = 4 \)

There are indeed three double bonds and a ring, making four in all. You would be wise to check that you can do these calculations without much trouble.

If you have other elements too it is simpler just to draw a trial structure and find out how many DBEs there are. You may prefer this method for all compounds as it has the advantage of finding one possible structure before you really start! One good tip is that if you have few hydrogens relative to the number of carbon atoms (and at least four DBEs) then there is probably an aromatic ring in the compound.
An unknown compound from a chemical reaction

Our second example addresses a situation very common in chemistry—working out the structure of a product of a reaction. The situation is this: you have treated propenal (acrolein) with HBr in ethane-1,2-diol (or glycol) as solvent for one hour at room temperature. Distillation of the reaction mixture gives a colourless liquid, compound X. What is it?

### Working out the DBEs for an unknown compound

1. Calculate the expected number of Hs in the saturated structure
   - (a) For $C_n$ there would be: $2n + 2$ Hs if C, H, O only
   - (b) For $C_nN_m$ there would be $2n + 2 + m$ Hs

2. Subtract the actual number of Hs and divide by 2. This gives the DBEs

3. If there are other atoms (Cl, B, P, etc.) it is best to draw a trial structure

4. If there are few Hs, e.g. less than the number of Cs, suspect a benzene ring

5. A benzene ring has *four* DBEs (three for the double bonds and one for the ring)

6. A nitro group has *one* DBE only

---

**mass spectrometry of compound X**

 mass spectrometry of compound X

**$^{13}$C NMR spectrum for propenal**

**$^{13}$C NMR spectrum for compound X**
The mass spectrum shows a molecular ion (181) much heavier than that of the starting material, \( \text{C}_3\text{H}_4\text{O} = 56 \). Indeed it shows two molecular ions at 181/179 typical of a bromo-compound, so it looks as if HBr has added to the aldehyde somehow. High resolution reveals a formula of \( \text{C}_5\text{H}_9\text{BrO}_2 \) and the five carbon atoms make it look as though the glycol has added in too. If we add everything together we find that the unknown compound is the result of the three reagents added together less one molecule of water. A trial structure reveals one DBE.

\[
\text{CH}_2=\text{CH}-\text{CHO} + \text{HOCH}_2\text{OH} + \text{HBr} \rightarrow \text{C}_5\text{H}_9\text{BrO}_2
\]

The next thing is to see what remains of the propenal. The NMR spectrum of \( \text{CH}_2=\text{CH}-\text{CHO} \) clearly shows one carbonyl group and two carbons on a double bond. These have all disappeared in the product and for the five carbon atoms we are left with four signals, two saturated, one next to oxygen, and one at 102.6 p.p.m. just creeping into the double bond region. It can’t be an alkene as an alkene is impossible with only one carbon atom! The IR spectrum gives us another puzzle—there appear to be no functional groups at all! No OH, no carbonyl, no alkene—what else can we have? The answer is an ether—or rather two ethers as there are two oxygen atoms. Now that we suspect an ether, we can look for the C–O single bond stretch in the IR spectrum and find it at 1128 cm\(^{-1}\). Each ether oxygen must have a carbon atom on each side of it. Two of these could be the same, but where are the rest?

We can solve this problem with a principle you may have guessed at before. If one oxygen atom takes a saturated carbon atom downfield to 50 p.p.m. or more, what could take a carbon downfield to 100 p.p.m. or more? We have established that chemical shifts are roughly additive so two oxygen atoms would just do. This would give us a fragment C–O–C–O–C accounting for three of the five carbon atoms. If you try and join the rest up with this fragment, you will find that you can’t do it without a double bond, for example, the structure in the margin.

But we know we haven’t got a double bond, (no alkene and no C=O) so the DBE must be a ring. You might feel uncomfortable with rings, but you must get used to them. Five-, six-, and seven-membered rings are very common. In fact, most known organic compounds have rings in them. We could join the skeleton of the present molecule up in many rings of various sizes like this one in the margin.

But this won’t do as it would have five different carbon atoms. It is much more likely that the basic skeletons of the organic reagents are preserved, that is, that we have a two-carbon and a three-carbon fragment joined through oxygen atoms. This gives four possibilities.
These are all quite reasonable, though we might prefer the third as it is easier to see how it derives from the reagents. A decision can easily be reached from the base peak in the mass spectrum at 73. This is a fragment corresponding to the five-membered ring and not to the six-membered ring. The product is in fact the third possibility.

Looking forward to Chapters 11 and 14

We have only begun to explore the intricate world of identification of structure by spectroscopy. It is important that you recognize that structures are assigned, not because of some theoretical reason or because a reaction ‘ought’ to give a certain product, but because of sound evidence from spectra. You have seen three powerful methods—mass spectra, \(^{13}\)C NMR, and IR spectroscopy in this chapter. In Chapter 11 we introduce the most important of all—proton (\(^{1}\)H) NMR and, finally, in Chapter 14 we shall take each of these a little further and show how the structures of more complex unknown compounds are really deduced. The last problem we have discussed here is not really solvable without proton NMR and in reality no-one would tackle any structure problem without this most powerful of all techniques. From now on spectroscopic evidence will appear in virtually every chapter. Even if we do not say so explicitly every time a new compound appears, the structure of this compound will in fact have been determined spectroscopically. Chemists make new compounds, and every time they do they characterize the compound with a full set of spectra. No scientific journal will accept that a new compound has been made unless a full description of all of these spectra are submitted with the report. Spectroscopy lets the science of organic chemistry advance.

Problems

1. How does the mass spectrum give evidence of isotopes in the compounds of bromine, chlorine, and carbon. Assuming the molecular ion of each of these compounds is of 100% abundance, what peaks (and in what intensity) would appear around that mass number? (a) \(\text{C}_2\text{H}_3\text{BrO}\), (b) \(\text{C}_6\text{H}_6\), (c) \(\text{C}_6\text{H}_4\text{BrCl}\). Give in cases (a) and (c) a possible structure for the compound. What compound is (b)?

2. The \(^{13}\)C NMR spectrum for ethyl benzoate contains these peaks: 17.3, 61.1, 100–150 p.p.m. (four peaks), and 166.8 p.p.m. Which peak belongs to which carbon atom?

3. The thinner used in typists’ correction fluids is a single compound, \(\text{C}_2\text{H}_3\text{Cl}_3\), having \(^{13}\)C NMR peaks at 45.1 and 95.0 p.p.m. What is its structure? A commercial paint thinner gives two spots on thin layer chromatography and has \(^{13}\)C NMR peaks at 7.0, 27.5, 35.2, 45.3, 95.6, and 206.3 p.p.m. Suggest what compounds might be used to make up this thinner.

4. The ‘normal’ O–H stretch (i.e. without hydrogen bonding) comes at about 3600 cm\(^{-1}\). What is the reduced mass (\(\mu\)) for O–H? What happens to the reduced mass when you double the atomic weight of each atom in turn, that is, what is \(\mu\) for O–D and what is \(\mu\) for S–H? In fact, both O–D and S–H stretches come at about 2500 cm\(^{-1}\).

5. Four compounds, each having the formula \(\text{C}_3\text{H}_5\text{NO}\), have the IR spectra summarized here. What are their structures? Without \(^{13}\)C NMR data, it may be easier to tackle this problem by first writing down all the possible structures for \(\text{C}_3\text{H}_5\text{NO}\). In what specific ways would \(^{13}\)C NMR data help?

   (a) One sharp band above 3000 cm\(^{-1}\); one strong band at about 1700 cm\(^{-1}\)
   (b) Two sharp bands above 3000 cm\(^{-1}\); two bands between 1600 and 1700 cm\(^{-1}\)
   (c) One strong broad band above 3000 cm\(^{-1}\); a band at about 2200 cm\(^{-1}\)

6. Four compounds having the molecular formula \(\text{C}_4\text{H}_6\text{O}_2\) have the IR and \(^{13}\)C NMR spectra given below. How many DBEs are there in \(\text{C}_4\text{H}_6\text{O}_2\)? What are the structures of the four compounds? You might again find it helpful to draw out some or all possibilities before you start.
Three compounds of molecular formula C₄H₈O have the IR and ¹³C NMR spectra given below. Suggest a structure for each compound, explaining how you make your deductions.

**compound A** IR: 1730 cm⁻¹; ¹³C NMR: 13.3, 15.7, 45.7, and 201.6 p.p.m.

**compound B** IR: 3200 (broad) cm⁻¹; ¹³C NMR: 36.9, 61.3, 117.2, and 134.7 p.p.m.

**compound C** IR: no peaks except CH and fingerprint; ¹³C NMR: 25.8 and 67.9 p.p.m.

**compound D** IR: 3200 (broad) cm⁻¹; ¹³C NMR: 15.2, 20.3, 36.0, and 62.9 p.p.m.

Compound A reacts with NaBH₄ to give compound D. Compound B reacts with hydrogen gas over a palladium catalyst to give the same compound D. Compound C reacts with neither reagent. Suggest a structure for compound D from the data given and explain the reactions. (Note: H₂ reduces alkenes to alkanes in the presence of a palladium catalyst.)

You have dissolved t-BuOH (Me₂COH) in MeCN with an acid catalyst, left the solution overnight, and found crystals with the following characteristics there in the morning. What are they?

**9.** How many isomers of trichlorobenzene are there? The 1,2,3-trichloro isomer is illustrated. Could they be distinguished by ¹³C NMR?

**10.** How many signals would you expect in the ¹³C NMR of the following compounds?

**11.** How would mass spectra help you distinguish these structures?
Note from the authors to all readers

This chapter contains mathematical material that some readers may find daunting. Organic chemistry students come from many different backgrounds since organic chemistry occupies a middle ground between the physical and the biological sciences. We hope that those from a more physical background will enjoy the material as it is. If you are one of those, you should work your way through the entire chapter. If you come from a more biological background, especially if you have done little maths at school, you may lose the essence of the chapter in a struggle to understand the equations. We have therefore picked out the more mathematical parts in boxes and you should abandon these parts (and any others!) if you find them too alien. The general principles behind the chapter—why molecules have the structures they do—are obviously so important that we cannot omit this essential material but you should try to grasp the principles without worrying too much about the equations. The ideas of atomic orbitals overlapping to form bonds, the molecular orbitals that result, and the shapes that these orbitals impose on organic molecules are at least as central for biochemistry as they are for organic chemistry. Please do not be discouraged but enjoy the challenge.

Introduction

You may recognize the model above as DNA, the molecule that carries the genetic information for all life on earth. It is the exact structure of this compound that determines precisely what a living thing
is—be it man or woman, frog, or tree—and even more subtle characteristics such as what colour eyes or hair people have.

What about this model?

You may also have recognized this molecule as buckminsterfullerene, a form of carbon that received enormous interest in the 1980s and 1990s. The question is, how did you recognize these two compounds? You recognized their shapes. All molecules are simply groups of atoms held together by electrons to give a definite three-dimensional shape. What exactly a compound might be is determined not only by the atoms it contains, but also by the arrangement of these atoms in space—the shape of the molecule. Both graphite and buckminsterfullerene are composed of carbon atoms only and yet their properties, both chemical and physical, are completely different.

There are many methods available to chemists and physicists to find out the shapes of molecules. One of the most recent techniques is called Scanning Tunnelling Microscopy (STM), which is the closest we can get to actually 'seeing' the atoms themselves.

Most techniques, for example, X-ray or electron diffraction, reveal the shapes of molecules indirectly.

In Chapter 3 you met some of the spectroscopic methods frequently used by organic chemists to determine the shape of molecules. Spectroscopy would reveal the structure of methane, for example, as tetrahedral—the carbon atom in the centre of a regular tetrahedron with the hydrogen atoms at the corners. In this chapter we are going to discuss why compounds adopt the shapes that they do.

This tetrahedral structure seems to be very important—other molecules, both organic and inorganic, are made up of many tetrahedral units. What is the origin of this tetrahedral structure? It could simply arise from four pairs of electrons repelling each other to get as far as possible from each other. That would give a tetrahedron.

The dark brown blobs in this STM picture recorded at a temperature of 4 K are individual oxygen atoms adsorbed on a silver surface. The light blobs are individual ethylene (ethene) molecules. Ethylene will only adsorb on silver if adjacent to an oxygen atom. This is an atomic scale view of a very important industrial process—the production of ethylene oxide from ethylene and oxygen using a silver catalyst.

The picture on the right is an X-ray structure of a catenane—a molecule consisting of two interlocking rings joined like two links in a chain. The key to the synthesis depends on the self-stacking of the planar structures prior to ring closure.

methane is tetrahedral
the H atoms form a tetrahedron
methane is tetrahedral
This simple method of deducing the structure of molecules is called Valence Shell Electron Pair Repulsion Theory (VSEPRT). It says that all electron pairs, both bonding and nonbonding, in the outer or valence shell of an atom repel each other. This simple approach predicts (more or less) the correct structures for methane, ammonia, and water with four electron pairs arranged tetrahedrally in each case.

VSEPRT seems to work for simple structures but surely there must be more to it than this? Indeed there is. If we really want to understand why molecules adopt the shapes they do, we must look at the atoms that make up the molecules and how they combine. By the end of this chapter, you should be able to predict or at least understand the shapes of simple molecules. For example, why are the bond angles in ammonia 107°, while in hydrides of the other elements in the same group as nitrogen, PH₃, AsH₃, and SbH₃, they are all around 90°? Simple VSEPRT would suggest tetrahedral arrangements for each.

Atomic structure

You know already what makes up an atom—protons, neutrons, and electrons. The protons and neutrons make up the central core of an atom—the nucleus—while the electrons form some sort of cloud around it. As chemists, we are concerned with the electrons in atoms and more importantly with the electrons in molecules: chemists need to know how many electrons there are in a system, where they are, and what energy they have. Before we can understand the behaviour of electrons in molecules, we need to look closely at the electronic structure of an atom. Evidence first, theory later.

Atomic emission spectra

Many towns and streets are lit at night by sodium vapour lamps. You will be familiar with their warm yellow-orange glow but have you ever wondered what makes this light orange and not white? The normal light bulbs you use at home have a tungsten filament that is heated white hot. You know that this white light could be split by a prism to reveal the whole spectrum of visible light and that each of the different colours has a different frequency that corresponds to a distinct energy. But where does the orange street light come from? If we put a coloured filter in front of our white light, it would absorb some colours of the spectrum and let other colours through. We could make orange light this way but that is not how the street lights work—they actually generate orange light and orange light only. Inside these lights is sodium metal. When the light is switched on, the sodium metal is slowly vaporized and, as an electric current is passed through the sodium vapour, an orange light is emitted. This is the same colour as the light you get when you do a flame test using a sodium compound.

The point is that only one colour light comes from a sodium lamp and this must have one specific frequency and therefore one energy. It doesn’t matter what energy source is used to generate the light, whether it be electricity or a Bunsen burner flame; in each case light of one specific energy is given out. Looking at the orange sodium light through a prism, we see a series of very sharp lines with two particularly bright orange lines at around 600 nm. Other elements produce similar spectra—indeed two elements, rubidium and cesium, were discovered by Robert Bunsen after studying such spectra. They are actually named after the presence of a pair of bright coloured lines in their spectra—cesium from the Latin caesius meaning bluish grey and rubidium from the Latin rubidus meaning red. Even hydrogen can be made to produce an atomic spectrum and, since a hydrogen atom is the simplest atom of all, we shall look at the atomic spectrum of hydrogen first.

If enough energy is supplied to a hydrogen atom, or any other atom, an electron is eventually knocked completely out of the atom. In the case of hydrogen a single proton is left. This is, of course, the ionization of hydrogen.

What if we don’t quite give the atom enough energy to remove an electron completely? It’s not too hard to imagine that, if the energy is not enough to ionize the atom, the electron would be
‘loosened’ in some way—the atom absorbs this energy and the electron moves further away from the nucleus and now needs less energy to remove it completely. The atom is said to be in an excited state. This process is a bit like a weight lifter lifting a heavy weight—he can hold it above his head with straight arms (the excited state) but sooner or later he will drop it and the weight will fall to the ground. This is what happens in our excited atom—the electron will fall to its lowest energy, its ground state, and the energy put in will come out again. This is the origin of the lines in the atomic spectra not only for hydrogen but for all the elements. The flame or the electric discharge provides the energy to promote an electron to a higher energy level and, when this electron returns to its ground state, this energy is released in the form of light.

Line spectra are composed of many lines of different frequencies, which can only mean that there must be lots of different energy transitions possible, but not just any energy transitions. Quantum mechanics says that an electron, like light, cannot have a continuous range of energies, only certain definite energies, which in turn means that only certain energy transitions are possible. This is rather like trying to climb a flight of stairs—you can jump up one, two, five, or even all the steps if you have enough energy but you cannot climb up half or two-thirds of a step. Likewise coming down, you can jump from one step to any other—lots of different combinations are possible but there is a finite number, depending on the number of steps. This is why there are so many lines in the atomic spectra—the electron can receive energy to promote it to a higher energy level and it can then fall to any level below and a certain quantity of light will be released.

We want to predict, as far as we can, where all the electrons in different molecules are to be found including the ones not involved with bonding. We want to know where the molecule can accommodate extra electrons and from where electrons can be removed most easily. Since most molecules contain many electrons, the task is not an easy one. However, the electronic structure of atoms is somewhat easier to understand and we can approximate the electronic structure of molecules by considering how the component atoms combine.

The next section is therefore an introduction to the electronic structure of atoms—what energies the electrons have and where they may be found. Organic chemists are rarely concerned with atoms themselves but need to understand the electronic structure in atoms before they can understand the electronic structure in molecules. As always, evidence first!

**The atomic emission spectrum of hydrogen**

The atomic emission spectrum of hydrogen is composed of many lines but these fall into separate sets or series. The first series to be discovered, not surprisingly, were those lines in the visible part of the spectrum. In 1885, a Swiss schoolmaster, Johann Balmer, noticed that the wavelengths, \( \lambda \), of the lines in this series could be predicted using a mathematical formula. He did not see why; he just saw the relationship. This was the first vital step.

\[
\lambda = \text{constant } \times \frac{n^2}{n^2 - 2^2} \quad (n \text{ is an integer greater than } 2)
\]

As a result of his work, the lines in the visible spectrum are known as the Balmer series. The other series of lines in the atomic emission spectrum of hydrogen were discovered later (the next wasn’t discovered until 1908). These series are named after the scientists who discovered them; for example, the series in the ultraviolet region is known as the Lyman series after Theodore Lyman.

Balmer’s equation was subsequently refined to give an equation that predicts the frequency, \( \nu \), of any of the lines in any part of the hydrogen spectrum rather than just for his series. It turns out that his was not the most fundamental series, just the first to be discovered.

\[
\nu = \text{constant } \times \left( \frac{1}{n_1^2} - \frac{1}{n_2^2} \right)
\]

Each series can be described by this equation if a particular value is given for \( n_1 \) but \( n_2 \) is allowed to vary. For the Lyman series, \( n_1 \) remains fixed at 1 while \( n_2 \) can be 2, 3, 4, and so on. For the Balmer series, \( n_1 \) is fixed at 2 while \( n_2 \) can be 3, 4, 5, and so on.
Atomic emission spectra are evidence for electronic energy levels

Atomic emission spectra give us our first clue to understanding the electronic energy levels in an atom. Since the lines in the emission spectrum of hydrogen correspond to the electron moving between energy levels and since frequency is proportional to energy, \( E = h \nu \), the early equations must represent just the difference between two energy levels. This in turn tells us that the electron’s energy levels in an atom must be inversely proportional to the square of an important integer ‘\( n \)’. This can be expressed by the formula

\[
E_n = -\frac{\text{constant}}{n^2}
\]

where \( E_n \) is the energy of an electron in the \( n \)th energy level and \( n \) is an integer \( \geq 1 \) known as the principal quantum number. Note that, when \( n = \infty \), that is, when the electron is no longer associated with the nucleus, its energy is zero. All other energy levels are lower than zero because of the minus sign in the equation. This is consistent with what we know already—we must put energy in to ionize the atom and remove the electron from the nucleus.

**Electronic energy levels**

In more detail, the constant in this equation can be broken down into a universal constant, the Rydberg constant \( R_H \), which applies to any electron on any atom, and a constant \( Z \) which has a particular value for each atom.

\[
E_n = -\frac{R_H Z^2}{n^2}
\]

The Rydberg constant \( R_H \) is measured in units of energy. For a given atom (i.e. \( Z \) is constant) there are many different energy levels possible (each corresponding to a different value of \( n \)). Also, as \( n \) gets bigger, the energy gets smaller and smaller and approaches zero for large \( n \). The energy gets smaller as the electron gets further away from the nucleus. For electrons in the same energy level but in different atoms, (i.e. keeping \( n \) constant but varying \( Z \)), the energy of an electron depends on the square of the atomic number. This makes sense too—the more protons in the nucleus, the more tightly the electron is held in the atom.

The electrons in any atom are grouped in energy levels whose energies are universally proportional to the inverse square of a very important number \( n \). This number is called the principal quantum number and it can have only a few integral values (\( n = 1, 2, 3 \ldots \)). The energy levels also depend on the type of atom.

An energy level diagram gives some idea of the relative spacing between these energy levels.

- The electrons in any atom can be grouped in energy levels whose energies are universally proportional to the inverse square of a very important number \( n \). This number is called the **principal quantum number** and it can have only a few integral values (\( n = 1, 2, 3 \ldots \)). The energy levels also depend on the type of atom.

---

Notice how the spacing between the energy levels gets closer and closer. This is a consequence of the energy being inversely proportional to the square of the principal quantum number. It tells us that it becomes easier and easier to remove an electron completely from an atom as the electron is located in higher and higher energy levels. As we shall see later, the increasing value of the principal quantum number also correlates with the electron being found (on average) further and further from the nucleus and being easier and easier to remove. This is analogous to a rocket escaping from a planet—the further away it is, the less it experiences the effects of gravity and so the less energy it requires to move still further away. The main difference is that there seems to be no quantization of the different energy levels of the rocket—it appears (to us in our macroscopic world at least) that any energy is possible. In the case of the electron in the atom, only certain values are allowed.
Three quantum numbers come from the Schrödinger equation

There is no doubt about the importance of \( n \), the principal quantum number, but where does it come from? This quantum number and two other quantum numbers come from solving the Schrödinger equation. We are not going to go into any details regarding Schrödinger’s equation or how to solve it—there are plenty of more specialized texts available if you are interested in more detail.

Solutions to Schrödinger’s equation come in the form of wave functions (symbol \( \Psi \)), which describe the energy and position of the electrons thought of as waves. You might be a little unsettled to find out that we are describing electrons using waves but the same wave–particle duality idea applies to electrons as to light. We regularly think of light in terms of waves with their associated wavelengths and frequencies but light can also be described using the idea of photons—individual little light ‘particles’. The same is true of the electron; up to now, you will probably have thought of electrons only as particles but now we will be thinking of them as waves.

It turns out that there is not one specific solution to the Schrödinger equation but many. This is good news because the electron in a hydrogen atom can indeed have a number of different energies. It turns out that each wave function can be defined by three quantum numbers (there is also a fourth quantum number but this is not needed to define the wave function). We have already met the principal quantum number, \( n \). The other two are called the orbital angular momentum quantum number (sometimes called the azimuthal quantum number), \( \ell \), and the magnetic quantum number, \( m_\ell \).

A specific wave function solution is called an orbital. The different orbitals define different energies and distributions for the different electrons. The name ‘orbital’ goes back to earlier theories where the electron was thought to orbit the nucleus in the way that planets orbit the sun. It seems to apply more to an electron seen as a particle, and orbitals of electrons thought of as particles and wave functions of electrons thought of as waves are really two different ways of looking at the same thing. Each different orbital has its own individual quantum numbers, \( n, \ell, \) and \( m_\ell \).

Summary of the importance of the quantum numbers

What does each quantum number tell us and what values can it adopt? You have already met the principal quantum number, \( n \), and seen that this is related to the energy of the orbital.

The principal quantum number, \( n \)

Different values for \( n \) divide orbitals into groups of similar energies called shells. Numerical values for \( n \) are used in ordinary speech. The first shell ( \( n = 1 \) ) can contain only two electrons and the atoms H and He have one and two electrons in this first shell, respectively.

The orbital angular momentum quantum number, \( \ell \)

The orbital angular momentum quantum number, \( \ell \), determines, as you might guess, the angular momentum of the electron as it moves in its orbital. This quantum number tells us the shape of the orbital, spherical or whatever. The values that \( \ell \) can take depend on the value of \( n \); \( \ell \) can have any value from 0 up to \( n - 1 \): \( \ell = 0, 1, 2, \ldots, n - 1 \). The different possible values of \( \ell \) are given letters rather than numbers and they are called s, p, d, and f.

The magnetic quantum number, \( m_\ell \)

The magnetic quantum number, \( m_\ell \), determines the spatial orientation of the angular momentum. In simple language it determines where the orbitals are in space. Its value depends on the value of \( \ell \), varying from \( -\ell \) to \( +\ell \): \( m_\ell = \ell, \ell - 1, \ell - 2, \ldots, -\ell \). The different possible values of \( m_\ell \) are given suffixes on the letters

defining the quantum number $\ell$. These letters refer to the direction of the orbitals along the $x$-, $y$-, or $z$-axes. Organic chemists are concerned mostly with $s$ and $p$ orbitals ($\ell = 0$ or 1) so the subdivisions of the $d$ orbitals can be omitted.

Each quantum number gives subdivisions for the one before. There are no subdivisions in the lowest value of each quantum number: and the subdivisions increase in number as each quantum number increases. Now we need to look in more detail at the meanings of the various values of the quantum numbers.

### Atomic orbitals

**Nomenclature of the orbitals**

For a hydrogen atom the energy of the orbital is determined only by the principal quantum number, $n$, and $n$ can take values 1, 2, 3, and so on. This is the most fundamental division and is stated first in the description of an electron. The electron in a hydrogen atom is called 1s$^1$. The 1 gives the value of $n$: the most important thing in the foremost place. The designation $s$ refers to the value of $\ell$. These two together, 1s, define and name the orbital. The superscript 1 tells us that there is one electron in this orbital.

The orbital angular momentum quantum number, $\ell$, determines the shape of the orbital. Instead of expressing this as a number, letters are used to label the different shapes of orbitals. $s$ orbitals have $\ell = 0$, and $p$ orbitals have $\ell = 1$.

Using both these quantum numbers we can label orbitals 1s, 2s, 2p, 3s, 3p, 3d, and so on. Notice that, since $\ell$ can only have integer values up to $n - 1$, we cannot have a 1p or 2d orbital.

One other point to notice is that, for the hydrogen atom (and, technically speaking, any one-electron ion such as He$^+$ or Li$^{2+}$), a 2s orbital has exactly the same energy as a 2p orbital and a 3s orbital has the same energy as the 3p and 3d orbitals. Orbitals that have the same energy are described as degenerate. In atoms with more than one electron, things get more complicated because of electron–electron repulsion and the energy levels are no longer determined by $n$ alone. In such cases, the 2s and 2p or the 3s, 3p, and 3d orbitals or any other orbitals that share the same principal quantum number are no longer degenerate. In other words, in multielectron atoms, the energy of a given orbital depends not only on the principal quantum number, $n$, but also in some way on the orbital angular momentum quantum number, $\ell$.

Values of the magnetic quantum number, $m_\ell$, depend on the value of $\ell$. When $\ell = 0$, $m_\ell$ can only take one value (0); when $\ell = 1$, $m_\ell$ has three possible values (+1, 0, or −1). There are five possible values of $m_\ell$ when $\ell = 2$ and seven when $\ell = 3$. In more familiar terms, there is only one sort of $s$ orbital; there are three sorts of $p$ orbitals, five sorts of $d$ orbitals, and seven sorts of $f$ orbitals. All three $p$ orbitals are degenerate as are all five $d$ orbitals and all seven $f$ orbitals (for both single-electron and multielectron atoms). We shall see how to represent these orbitals later.

### There is a fourth quantum number

The spin of an electron is the angular momentum of an electron spinning about its own axis, although this is a simplified picture. This angular momentum is different from the angular momentum, $\ell$, which represents the electron’s angular momentum about the nucleus. The magnitude of the electron’s spin is constant but it can take two orientations. These are represented using the fourth quantum number, the spin angular momentum quantum number, $m_\sigma$, which can take the value of +1 or −1 in any orbital, regardless of the values of $n$, $\ell$, or $m_\ell$. Each
orbital can hold a maximum of two electrons and then only when the electrons have different ‘spin’, that is, they must have different values of $m_s$, +1 or –1. The rule that no more than two electrons may occupy any orbital (and then only if their spins are paired) is known as the Pauli exclusion principle.

- **Every electron is unique!**
  If electrons are in the same atom, they must have a unique combination of the four quantum numbers. Each orbital, designated by three quantum numbers, $n$, $\ell$, and $m_\ell$, can contain only two electrons and then only if their spin angular quantum numbers are different.

### How the periodic table is constructed

All the quantum numbers for all the electrons with $n = 1$ and 2 can now be shown in a table like the ones earlier in this chapter. Though we have so far been discussing the hydrogen atom, in fact, the H atom never has more than two electrons. Fortunately, the energy levels deduced for H also apply to all the other elements with some minor adjustments. This table would actually give the electronic configuration of neon, Ne.

In this table, the energy goes up from left to right, though all the 2p orbitals are degenerate. To add $n = 3$, one column for the 3s, three columns for the 3p, and five columns for the 3d orbital would be needed. Then all five 3d orbitals would be degenerate.

Another way to show the same thing is by an energy diagram showing how the quantum numbers divide and subdivide.
These numbers explain the shape of the periodic table. Each element has one more electron (and one more proton and perhaps more neutrons) than the one before. At first the lowest energy shell ($n = 1$) is filled. There is only one orbital, 1s, and we can put one or two electrons in it. There are therefore two elements in this block, H and He. Next we must move to the second shell ($n = 2$), filling 2s first so we start the top of groups 1 and 2 with Li and Be. These occupy the top of the red stack marked ‘s block’ because all the elements in this block have one or two electrons in their outermost s orbital and no electrons in the outermost p orbital. Then we can start on the 2p orbitals. There are three of these so we can put in six electrons and get six elements B, C, N, O, F, and Ne. They occupy the top row of the black p block. Most of the elements we need in this book are in these blocks. Some, Na, K, and Mg for example, are in the s block and others, Si, P, and S for example, are in the second row of the p block.

The layout of the periodic table

Graphical representations of orbitals

One problem with wave functions is trying to visualize them: what does a wave function look like? Various graphs of wave functions can be plotted but they are not much help as $\Psi$ itself has no physical meaning. However the square of the wave function, $\Psi^2$, does have a practical interpretation; it is proportional to the probability of finding an electron at a given point. Unfortunately, we can’t do

There is some justification for this interpretation that the wave function squared is proportional to the probability of finding an electron. With light waves, for example, while the wavelength provides the colour (more precisely the energy) of the wave, it is the amplitude squared that gives the brightness.

But this is looking at light in terms of waves. In terms of particles, photons, the intensity of light is proportional to the density of photons.
better than probability as we are unable to say exactly where the electron is at any time. This is a consequence of Heisenberg’s uncertainty principle—we cannot know both the exact position and the exact momentum of an electron simultaneously. Here we know the momentum (energy) of the electron and so its exact position is uncertain.

How do we depict a probability function? One way would be to draw contours connecting regions where there is an equal probability of finding the electron. If $\Psi^2$ for a 1s orbital is plotted, a three-dimensional plot emerges. Of course, this is a two-dimensional representation of a three-dimensional plot—the contours are really spherical like the different layers of an onion. These circles are rather like the contour lines on a map except that they represent areas of equal probability of finding the electron instead of areas of equal altitude.

Another way to represent the probability is by a density plot. Suppose we could see exactly where the electron was at a given time and that we marked the spot. If we looked again a little later, the electron would be in a different place—let us mark this spot too. Eventually, if we marked enough spots, we would end up with a fuzzy picture like those shown for the 1s and 2s orbitals. Now the density of the dots is an indication of the probability of finding an electron in a given space—the more densely packed the dots (that is, the darker the area), the greater the probability of finding the electron in this area. This is rather like some maps where different altitudes are indicated by different colours.

The 2s orbital, like the 1s orbital, is spherical. There are two differences between these orbitals. One is that the 2s orbital is bigger so that an electron in a 2s orbital is more likely to be found further away from the nucleus than an electron in a 1s orbital. The other difference between the orbitals is that, within the 2s orbital but not within the 1s orbital, there is a region where there is no electron density at all. Such a region is called a nodal surface. In this case there is no electron density at one set radius from the nucleus; hence this is known as a radial node. The 2s orbital has one radial node.

Nodes are important for musicians

You can understand these nodal surfaces by thinking in terms of waves. If a violin or other string instrument is plucked, the string vibrates. The ends cannot move since they are fixed to the instrument. The note we hear is mainly due to the string vibrating as shown in the diagram for the first harmonic.

However, there are other vibrations of higher energy known as harmonics, which help to give the note its timbre (the different timbres allow us to tell the difference between, say, a flute and a violin playing the same note). The second and third harmonics are also shown.

Each successive harmonic has one extra node—while the first harmonic has no nodes (if you don’t count the end stops), the second harmonic has one and the third has two and so on. These are points where the string does not vibrate at all (you can even ‘select out’ the second harmonic on a stringed instrument if you gently press halfway along the vibrating string).
What does a \( \Psi^2 \) for a 2p orbital look like? The probability density plot is no longer spherically symmetrical. This time the shape is completely different—the orbital now has an orientation in space and it has two lobes. Notice also that there is a region where there is no electron density between the two lobes—another nodal surface. This time the node is a plane in between the two lobes and so it is known as a nodal plane. One representation of the 2p orbitals is a three-dimensional plot, which gives a clear idea of the true shape of the orbital.

Plots of 3p and 4p orbitals are similar—each has a nodal plane and the overall shape outlined in each is the same. However, the 3p orbital also has a radial node and the 4p has two radial nodes and once again the size of the orbital increases as the principal quantum number increases.

All this explains why the shape of an orbital depends on the orbital angular quantum number, \( \ell \). All s orbitals (\( \ell = 0 \)) are spherical, all p orbitals (\( \ell = 1 \)) are shaped like a figure eight, and d orbitals (\( \ell = 2 \)) are yet another different shape. The problem is that these probability density plots take a long time to draw—organic chemists need a simple easy way to represent orbitals. The contour diagrams were easier to draw but even they were a little tedious. Even simpler still is to draw just one contour within which there is, say, a 90% chance of finding the electron. This means that all s orbitals can be represented by a circle, and all p orbitals by a pair of lobes.

**The phase of an orbital**

The wave diagrams need further discussion to establish one fine point—the phase of an orbital.

Just as an electromagnetic wave, or the wave on a vibrating string, or even an ocean wave possesses different ‘phases’ (for example, the troughs and peaks of an ocean wave) so too do the atom’s wave functions—the orbitals. After each node in an orbital, the phase of the wave function changes. In the
2p orbital, for example, one lobe is one phase; the other lobe is another phase with the nodal plane in between. In the standing wave above the different phases are labelled positive and negative. The phases of a p orbital could be labelled in the same way (and you may sometimes see this) but, since chemists use positive and negative signs to mean specific charges, this could get confusing. Instead, one half of the p orbital is usually shaded to show that it has a different phase from the other half.

The magnetic quantum number, $m_\ell$

The magnetic quantum number, $m_\ell$, determines the spatial orientation of the orbital’s angular momentum and takes the values $-\ell$ to $+\ell$. An s orbital ($\ell = 0$), being spherical, can only have one orientation in space—it does not point in any one direction and hence it only has one value for $m_\ell (0)$. However, a p orbital could point in any direction. For a p orbital ($\ell = 1$) there are three values of $m_\ell = -1, 0, +1$. These correspond to the p orbitals aligned along the mutually perpendicular $x$-, $y$-, and $z$-axes. These orbitals, designated $p_x$, $p_y$, and $p_z$, are all degenerate. They differ only in their spatial orientations.

Summary so far

- Electrons in atoms are best described as waves
- All the information about the wave (and hence about the electron) is in the wave function, $\Psi$, the solution to the Schrödinger equation
- There are many possible solutions to the Schrödinger equation but each wave function (also called an orbital) can be described using three quantum numbers
- The principal quantum number, $n$, is largely responsible for the energy of the orbital (in one-electron systems, such as the hydrogen atom, it alone determines the energy). It takes integer values 1, 2, 3, 4, and so on, corresponding to the first, second, third, and so on shells of electrons
- The orbital angular momentum quantum number, $\ell$, determines the angular momentum that arises from the motion of an electron moving in the orbital. Its value depends on the value of $n$ and it takes integer values $0, \ldots, n-1$ but the orbitals are usually known by letters ($s$ when $\ell = 0$, $p$ when $\ell = 1$, $d$ when $\ell = 2$, and $f$ when $\ell = 3$). Orbitals with different values of $\ell$ have different shapes—s orbitals are spherical, p orbitals are shaped like a figure of eight
- The magnetic quantum number, $m_\ell$, determines the spatial orientation of the orbital. Its value depends on the value of $\ell$ and it can take the integer values: $-\ell, \ldots, 0, \ldots, +\ell$. This means that there is only one type of s orbital, three different p orbitals (all mutually perpendicular), five different d orbitals, and seven different f orbitals. The three different p orbitals are all degenerate, that is, they have the same energy (as do the five d orbitals and the seven f orbitals)
There is also a fourth quantum number, the spin angular momentum quantum number, $m_s$, which can take values of +1 or −1. The spin is not a property of orbitals but of the electrons that we put in the orbitals.

No two electrons in any one atom can have all four quantum numbers the same—this means that each orbital as described by the (first) three quantum numbers can hold a maximum of two electrons and then only if they have opposing spins.

We usually use a shorthand notation to describe an orbital such as 1s or 2p_y.

The number tells us the principal quantum number, $n$.

The letter tells us the orbital angular momentum quantum number, $l$.

The subscript letter tells us the magnetic quantum number, $m_l$.

These three quantum numbers, $n$, $l$, and $m_l$, define an orbital.

A few points are worth emphasis. Orbitals do not need to have electrons in them—they can be vacant (there doesn’t have to be someone standing on a stair for it to exist!). So far we have mainly been talking about the hydrogen atom and this has only one electron. Most of the time this electron is in the 1s orbital (the orbital lowest in energy) but if we give it enough energy we can promote it to a vacant orbital higher in energy, say, for example, the 3p_x orbital.

Another point is that the electrons may be found anywhere in an orbital except in a node. In a p orbital containing one electron, this electron may be found on either side but never in the middle. When the orbital contains two electrons, one electron doesn’t stay in one half and the other electron in the other half—both electrons could be anywhere (except in the node).

Finally, remember that all these orbitals are superimposed on each other. The 1s orbital is not the middle part of the 2s orbital. The 1s and 2s orbitals are separate orbitals in their own rights and each can hold a maximum of two electrons but the 2s orbital does occupy some of the same space as the 1s orbital (and also as the 2p orbitals, come to that). Neon, for example, has ten electrons in total: two will be in the 1s orbital, two in the 2s orbital, and two in each of the 2p orbitals. All these orbitals are superimposed on each other but the pairs of electrons are restricted to their individual orbitals. If we tried to draw all these orbitals, superimposed on each other as they are, in the same diagram the result would be a mess!

Putting electrons in orbitals

Working out where the electrons are in any atom, that is, which orbitals are populated, is easy. We simply put two electrons into the lowest energy orbital and work upwards. This ‘building up’ of the different atoms by putting electrons in the orbitals until they are full and then filling up the orbital next lowest in energy is known as the **Aufbau principle** (**Aufbau** is German for ‘building up’). The first and only electron in the hydrogen atom must go into the 1s orbital. In this sort of diagram the energy levels are represented as horizontal lines stacked roughly in order with the lowest energy at the bottom. Electrons are represented as vertical arrows. Arrows pointing upwards show one spin ($m_s = +1$ or −1) and arrows pointing downwards the other (which is which doesn’t matter).
The helium atom has two electrons and they can both fit into the 1s orbital providing they have opposite spins. The other change to the diagram is that, with two electrons and electron repulsion a factor, the 2s orbital is now lower in energy than the three 2p orbitals, though these three are still degenerate.

Lithium has one more electron but the 1s orbital is already full. The third electron must go into the next lowest orbital and that is the 2s. In this three-electron system, like that of the two-electron He atom, the three 2p orbitals are higher in energy than the 2s orbital. By the time we come to boron, with five electrons, the 2s is full as well and we must put the last electron into a 2p orbital. It doesn’t matter which one; they are degenerate.

Carbon has one more electron than boron but now there is a bit of a problem—where does the last electron go? It could either be paired with the electron already in one of the p orbitals or it could go into one of the other degenerate p orbitals. It turns out that the system is lower in energy (electron–electron repulsion is minimized) if the electrons are placed in different degenerate orbitals with their spins parallel (that is, both spins +1 or both –1). Another way of looking at this is that putting two electrons into the same orbital with their spins paired (that is, one +1, one –1) requires some extra amount of energy, sometimes called pairing energy.

This is known as Hund’s rule. An atom adopts the electronic configuration that has the greatest number of unpaired electrons in degenerate orbitals. Whilst this is all a bit theoretical in that isolated atoms are not found very often, the same rule applies for electrons in degenerate orbitals in molecules.
Nitrogen, with one more electron than carbon, has a single electron in each of the 2p orbitals. The new electron pairs up with another already in one of the 2p orbitals. It doesn’t enter the 3s orbital (the orbital next lowest in energy) since this is so much higher in energy and to enter the 3s orbital would require more energy than that needed to pair up with a 2p electron.

Molecular orbitals—homonuclear diatomics

So far the discussion has concerned only the shapes and energies of atomic orbitals (AOs). Organic chemists really need to look at the orbitals for whole molecules. One way to construct such molecular orbitals (MOs) is to combine the atomic orbitals of the atoms that make up the molecule. This approach is known as the Linear Combination of Atomic Orbitals (LCAO).

Atomic orbitals are wave functions and the different wave functions can be combined together rather in the way waves combine. You may be already familiar with the ideas of combining waves—they can add together constructively (in-phase) or destructively (out-of-phase).

Atomic orbitals can combine in the same way—in-phase or out-of-phase. Using two 1s orbitals drawn as circles (representing spheres) with dots to mark the nuclei and shading to represent phase, we can combine them in-phase, that is, add them together, or out-of-phase when they cancel each other out in a nodal plane down the centre between the two nuclei. The resulting orbitals belong to both atoms—they are molecular rather than atomic orbitals. As usual, the higher energy orbital is at the top.
When the two orbitals combine out-of-phase, the resulting molecular orbital has a nodal plane between the two nuclei. This means that if we were to put electrons into this orbital there would be no electron density in between the two nuclei. By contrast, if the molecular orbital from in-phase combination contained electrons, they would be found in between the two nuclei. Two exposed nuclei repel each other as both are positively charged. Any electron density between them helps to bond them together. So the in-phase combination is a bonding molecular orbital. As for the electrons themselves, they can now be shared between two nuclei and this lowers their energy relative to the 1s atomic orbital. Electrons in the orbital from the out-of-phase combination do not help bond the two nuclei together; in fact, they hinder the bonding. When this orbital is occupied, the electrons are mainly to be found anywhere but between the two nuclei. This means the two nuclei are more exposed to each other and so repel each other. This orbital is known as an antibonding molecular orbital and is higher in energy than the 1s orbitals.

The combination of the atomic 1s orbitals to give the two new molecular orbitals is simply shown on an energy level diagram. With one electron in each 1s orbital, two hydrogen atoms combine to give a hydrogen molecule.

There are several points to notice about this diagram.

- Two atomic orbitals (AOs) combine to give two molecular orbitals (MOs)
- By LCAO we add the two AOs to make the bonding orbital and subtract them to make the antibonding orbital
- Since the two atoms are the same, each AO contributes the same amount to the MOs
- The bonding MO is lower in energy than the AOs
- The antibonding MO is higher in energy than the AOs
- Each hydrogen atom initially had one electron. The spin of these electrons is unimportant
• The two electrons end up in the MO lowest in energy. This is the bonding MO
• Just as with AOs, each MO can hold two electrons as long as the electrons are spin paired
• The two electrons between the two nuclei in the bonding MO hold the molecule together—they are the chemical bond
• Since these two electrons are lower in energy in the MO than in the AOs, energy is given out when the atoms combine
• Or, if you prefer, we must put in energy to separate the two atoms again and to break the bond

From now on, we will always represent molecular orbitals in energy order—the highest-energy MO at the top (usually an antibonding MO) and the lowest in energy (usually a bonding MO and the one in which the electrons are most stable) at the bottom. We suggest you do the same.

When we were looking at the electronic configuration of atoms, we simply filled up the atomic orbitals starting from the lowest in energy and worked up. With molecules we do the same: we just fill up the molecular orbitals with however many electrons we have, starting from the lowest in energy and remembering that each orbital can hold two electrons and then only if they are spin paired.

**Breaking bonds**

If an atom is supplied with energy, an electron can be promoted to a higher energy level and it can then fall back down to its ground state, giving that energy out again. What would happen if an electron were promoted in a hydrogen molecule from the lowest energy level, the bonding MO, to the next lowest energy level, the antibonding MO? Again, an energy level diagram helps.

Now the electron in the antibonding orbital ‘cancels out’ the bonding of the electron in the bonding orbital. Since there is no overall bonding holding the two atoms together, they can drift apart as two separate atoms with their electrons in 1s atomic orbitals. In other words, promoting an electron from the bonding MO to the antibonding MO breaks the chemical bond. This is difficult to do with hydrogen molecules but easy with, say, bromine molecules. Shining light on \( \text{Br}_2 \) causes it to break up into bromine atoms.

**Bonding in other elements: helium**

A hydrogen molecule is held together by a single chemical bond since the pair of electrons in the bonding orbital constitutes this single bond. What would the MO energy level diagram for \( \text{He}_2 \) look like? Each helium atom has two electrons \((1s^2)\) so now both the bonding MO and the antibonding MO are full. Any bonding due to the electrons in the bonding orbital is cancelled out by the electrons in the antibonding orbital.

This idea will be developed in Chapters 5 and 6 when we look at bond-breaking steps in organic reaction mechanisms.
There is no overall bonding, the two helium atoms are not held together, and He$_2$ does not exist. Only if there are more electrons in bonding MOs than in antibonding MOs will there be any bonding between two atoms. In fact, we define the number of bonds between two atoms as the bond order (dividing by two since two electrons make up a chemical bond).

\[
\text{bond order} = \frac{(\text{no. of electrons in bonding MOs}) - (\text{no. of electrons in antibonding MOs})}{2}
\]

Hence the bond orders for H$_2$ and He$_2$ are

\[
\text{bond order (H}_2) = \frac{2-0}{2} = 1 \quad \text{i.e. a single bond}
\]
\[
\text{bond order (He}_2 = \frac{2-2}{2} = 0 \quad \text{i.e. no bond}
\]

**Bond formation using 2s and 2p atomic orbitals**

So far we have been looking at how we can combine the 1s atomic orbitals to give the molecular orbitals of simple molecules. However, just as there are lots of higher, vacant energy levels in atoms, so there are in molecules too. Other atomic orbitals combine to give new molecular orbitals and the 2s and 2p orbitals concern organic chemistry most of all. The 2s AOs combine in exactly the same way as the 1s orbitals do and also give rise to a bonding and an antibonding orbital. With p orbitals as well, there are more possibilities.

Since we are beginning to talk about lots of different MOs, we shall need to label them with a little more thought. When s orbitals combine, the resulting MOs, both bonding and antibonding, are totally symmetrical about the axis joining the two nuclei.

Antibonding orbitals are designated with a * e.g. $\sigma^*$, or $\pi^*$

Both MOs have rotational symmetry about the axis through the two nuclei.

When orbitals combine in this end-on overlap to give cylindrically symmetrical MOs, the resulting orbitals are said to possess sigma ($\sigma$) symmetry. Hence the bonding MO is a sigma orbital and electrons in such an orbital give rise to a sigma bond. In the hydrogen molecule the two hydrogen atoms are joined by a $\sigma$ bond.
What MOs result from the combination of two p orbitals? There are three mutually perpendicular p orbitals on each atom. As the two atoms approach each other, these orbitals can combine in two different ways—one p orbital from each atom can overlap end-on, but the other two p orbitals on each atom must combine side-on.

The end-on overlap (in-phase and out-of-phase) results in a pair of MOs that are cylindrically symmetrical about the internuclear axis—in other words, these combinations have $\sigma$ symmetry. The two molecular orbitals resulting from the end-on combination of two 2p orbitals are labelled the 2p$\sigma$ and the 2p$\sigma^*$ MOs.

The side-on overlap of two p orbitals forms an MO that is no longer symmetrical about the internuclear axis. If we rotate about this axis, the phase of the orbital changes. The orbital is described as having $\pi$ symmetry—a $\pi$ orbital is formed and the electrons in such an orbital make up a $\pi$ bond. Since there are two mutually perpendicular pairs of p orbitals that can combine in this fashion, there are a pair of degenerate mutually perpendicular $\pi$ bonding MOs and a pair of degenerate mutually perpendicular $\pi^*$ antibonding MOs.

The two sorts of molecular orbitals arising from the combinations of the p orbitals are not degenerate—more overlap is possible when the AOs overlap end-on than when they overlap side-on. As a
result, the $p_\sigma$ orbital is lower in energy than the $p_\pi$ orbital. We can now draw an energy level diagram to show the combination of the 1s, 2s, and 2p atomic orbitals to form molecular orbitals.

Let us now look at a simple diatomic molecule—nitrogen. A nitrogen molecule is composed of two nitrogen atoms, each containing seven electrons in total. We shall omit the 1s electrons because they are so much lower in energy than the electrons in the 2s and 2p AOs and because it makes no difference in terms of bonding since the electrons in the $1s_\sigma^*$ cancel out the bonding due to the electrons in the $1s_\sigma$ MO. The electrons in the 1s AOs and the 1s MOs are described as core electrons and so, in discussing bonding, we shall consider only the electrons in the outermost shell, in this case the 2s and 2p electrons. This means each nitrogen contributes five bonding electrons and hence the molecular orbitals must contain a total of ten electrons.

The electrons in the $\sigma$ and $\sigma^*$ MOs formed from the 2s MOs also cancel out—these electrons effectively sit on the atoms, two on each, and form lone pairs—nonbonding pairs of electrons that do not contribute to bonding. All the bonding is done with the remaining six electrons. They fit neatly into a $\sigma$ bond from two of the $p$ orbitals and two $\pi$ bonds from the other two pairs. Nitrogen has a triple bonded structure.

**Heteronuclear diatomics**

Up to now we have only considered combining two atoms of the same element to form homonuclear diatomic molecules. Now we shall consider what happens when the two atoms are different. First of all, how do the atomic orbitals of different elements differ? They have the same sorts of orbitals 1s, 2s, 2p, etc. and these orbitals will be the same shapes but the orbitals will have different energies. For
example, removing an electron completely from atoms of carbon, oxygen, or fluorine (that is, ionizing the atoms) requires different amounts of energy. Fluorine requires most energy, carbon least, even though in each case we are removing an electron from the same orbital, the 2p AO. The energies of the 2p orbitals must be lowest in fluorine, low in oxygen, and highest in carbon.

We are talking now about electronegativity. The more electronegative an atom is, the more it attracts electrons. This can be understood in terms of energies of the AOs. The more electronegative an atom is, the lower in energy are its AOs and so any electrons in them are held more tightly. This is a consequence of the increasing nuclear charge going from left to right across the periodic table. As we go from Li across to C and on to N, O, and F, the elements steadily become more electronegative and the AOs lower in energy.

So what happens if two atoms whose atomic orbitals were vastly different in energy, such as Na and F, were to combine? An electron transfers from sodium to fluorine and the product is the ionic salt, sodium fluoride, $\text{NaF}$.

The important point is that the atomic orbitals are too far apart in energy to combine to form a new molecular orbital and no covalent bond is formed. The ionic bonding in NaF is due simply to the attraction between two oppositely charged ions. When the atomic orbitals have exactly the same energy, they combine to form new molecular orbitals, one with an energy lower than the AOs, the other with an energy higher than the AOs. When the AOs are very different in energy, electrons are transferred from one atom to another and ionic bonding results. When the AOs are slightly different in energy, they do combine and we need now to look at this situation in more detail.
The AOs combine to form new MOs but they do so unsymmetrically. The more electronegative atom, perhaps O or F, contributes more to the bonding orbital and the less electronegative element (carbon is the one we shall usually be interested in) contributes more to the antibonding orbital. This applies both to $\sigma$ bonds and to $\pi$ bonds so here is an idealized case.

These three different cases where the two combining orbitals differ greatly in energy, only a little, or not at all are summarized below.

### Energies of AOs both the same
- Large interaction between AOs
- Bonding MO much lower in energy than AOs
- Antibonding MO is much higher in the energy than the AOs
- Both AOs contribute equally to the MOs
- Electrons in bonding MO are shared equally between the two atoms
- Bond between A and B would classically be described as purely covalent
- Easiest to break bond into two radicals (homolytic fission). Heterolytic fission of bond is possible and could give either $A^+$ and $B^-$ or $A^-$ and $B^+$

### AO on atom B is a little lower in energy than AO on atom A
- Less interaction between AOs
- Bonding MO is lowered only by a small amount relative to AO on atom B
- Antibonding MO is raised in energy by only a small amount relative to AO on atom B
- The AO on B contributes more to the bonding MO and the AO on A electrons in bonding MO are shared between atoms but are associated more with atom B than A
- Bond between A and B is covalent but there is also some electrostatic (ionic) attraction between atoms
- Easiest to break bond into two ions, $A^+$ and $B^-$, although it is also possible to give two radicals

### AO on atom B is a lot lower in energy than AO on atom A
- AOs are too far apart in energy to interact
- The filled orbital on the anion has the same energy as the AO on atom B
- The empty orbital on the cation has the same energy as the AO on atom A
- Only one AO contributes to each ‘MO’
- Electrons in the filled orbital are located only on atom B
- Bond between A and B would classically be described as purely ionic
- Compound already exists as ions $A^+$ and $B^-$
As an example of atomic orbitals of equal and unequal energies combining, let us consider the $\pi$ bonds resulting from two carbon atoms combining and from a carbon atom combining with an oxygen atom. With the C–C $\pi$ bond, both p orbitals have the same energy and combine to form a symmetrical $\pi$ bond. If the bonding MO ($\pi$) is occupied, the electrons are shared equally over both carbon atoms. Compare this with the $\pi$ bond that results from combining an oxygen p AO with a carbon p AO.

Now the bonding MO ($\pi$) is made up with a greater contribution from the oxygen p orbital than from the carbon p orbital. If this MO contained electrons, there would be more electrons around the oxygen atom than around the carbon. This C–O $\pi$ bond is covalent but there is also some electrostatic contribution to its bond strength. This electrostatic interaction actually makes a C–O double bond much stronger than a C–C double bond (bond strength for C=O, about 725–60 kJ mol$^{-1}$; for C=C, 600–25 kJ mol$^{-1}$; compare also a C–O single bond, 350–80 kJ mol$^{-1}$ with a C–C single bond, 340–50 kJ mol$^{-1}$). Because the electrons in the populated MO ($\pi$) are associated more with the oxygen atom than with the carbon, it is easier to break this bond heterolytically with both electrons moving completely on to the oxygen atom than it is to break it homolytically to get a diradical with one electron moving on to the carbon and one on to the oxygen atom. This will be the first chemical reaction we study in detail in Chapters 5 and 6.

Other factors affecting degree of orbital interaction

Having similar energies is not the only criterion for good interaction between two atomic orbitals. It also matters how the orbitals overlap. We have seen that p orbitals overlap better in an end-on fashion (forming a $\sigma$ bond) than they do side-on (forming a $\pi$ bond). Another factor is the size of the atomic orbitals. For best overlap, the orbitals should be the same size—a 2p orbital overlaps much better with another 2p orbital than it does with a 3p or 4p orbital.

A third factor is the symmetry of the orbitals—two atomic orbitals must have the appropriate symmetry to combine. Thus a 2p$_x$ orbital cannot combine with a 2p$_y$ or 2p$_z$ orbital since they are all perpendicular to each other (they are orthogonal). In one case the two p orbitals have no overlap at all; in the other case any constructive overlap is cancelled out by equal amounts of destructive overlap.
overlap. Likewise, an s orbital can overlap with a p orbital only end-on. Sideways overlap leads to equal amounts of bonding and antibonding interactions and no overall gain in energy.

**Molecular orbitals of molecules with more than two atoms**

We now need to look at ways of combining more than two atoms at a time. For some molecules, such as H₂S and PH₃, that have all bond angles equal to 90°, the bonding should be straightforward—the p orbitals (which are at 90°) on the central atom simply overlap with the 1s orbitals of the hydrogen atoms.

But how do we account for the bond angles in water (104°) and ammonia (107°) when the only atomic orbitals are at 90° to each other? All the covalent compounds of elements in the row Li to Ne raise this difficulty. Water (H₂O) and ammonia (NH₃) have angles between their bonds that are roughly tetrahedral and methane (CH₄) is exactly tetrahedral but how can the atomic orbitals combine to rationalize this shape? The carbon atom has electrons only in the first and second shells, and the 1s orbital is too low in energy to contribute to any molecular orbitals, which leaves only the 2s and 2p orbitals. The problem is that the 2p orbitals are at right angles to each other and methane does not have any 90° bonds. (So don’t draw any either! Remember Chapter 2.). Let us consider exactly where the atoms are in methane and see if we can combine the AOs in such a way as to make satisfactory molecular orbitals.

Methane has a tetrahedral structure with each C–H bond 109 pm and all the bond angles 109.5°. To simplify things, we shall draw a molecule of methane enclosed in a cube. It is possible to do this since the opposite corners of a cube describe a perfect tetrahedron. The carbon atom is at the centre of the cube and the four hydrogen atoms are at four of the corners.

Now, how can the carbon’s 2s and 2p atomic orbitals combine with the four hydrogen 1s atomic orbitals? The carbon’s 2s orbital can overlap with all four hydrogen 1s orbitals at once with all the orbitals in the same phase. In more complicated systems like this, it is clearer to use a diagram of the AOs to see what the MO will be like.

Each of the 2p orbitals points to opposite faces of the cube. Once more all four hydrogen 1s orbitals can combine with each p orbital but this time the hydrogen AOs on the opposite faces of the cube must be differently phased.

Again we are not going to draw these three molecular orbitals but you can see from the AO diagrams what they look like. They are degenerate (that is, they have the same energy) and each orbital has one nodal plane (it is easiest to see in the middle diagram passing vertically down the middle of the cube and dividing shaded orbitals on the right from unshaded orbitals on the left). Only the bonding overlap between the AOs is shown but of course there is an antibonding interaction for
every bonding interaction, which means there are eight MOs altogether (which is correct since there were eight AOs to start with).

Organic chemists can just about understand this ‘correct’ MO picture of methane and theoretical chemists are able to construct correct MOs for very much more complex molecules than methane. There is experimental evidence too that these pictures are correct. Other experiments reveal that all four C–H bonds in methane are exactly the same and yet the MOs for methane are not all the same. There is no contradiction here! The molecular orbital approach tells us that there is one MO of one kind and three of another but the electrons in them are shared out over all five atoms. No one hydrogen atom has more or less electrons than any other—they are all equivalent. Techniques that tell us the structure of methane do not tell us where bonds are; they simply tell us where the atoms are located in space—we draw in bonds connecting atoms together. Certainly the atoms form a regular tetrahedron but exactly where the electrons are is a different matter entirely. The classical picture of two atoms held together by a pair of electrons is not necessarily correct—the five atoms in methane are held together by electrons but these are in molecular orbitals, which spread over all the atoms. We are going to need the classical picture when we draw mechanisms. Methane only has one carbon atom—imagine what it would be like with larger compounds that can contain hundreds of carbon atoms! Fortunately, there is another, simpler method we can use to describe bonding that preserves the important points from this theory.

**Hybridization of atomic orbitals**

For most of organic chemistry, it is helpful to consider the molecule as being made up of atoms held together by bonds consisting of a pair of electrons. When working out the MOs for methane, we used the carbon 2s and all three of the 2p orbitals to combine with the hydrogen 1s orbitals. Each orbital combined with all the hydrogen orbitals equally. Another way to consider the bonding would be to combine the carbon 2s and 2p orbitals first to make four new orbitals. Each of these orbitals would be exactly the same and be composed of one-quarter of the 2s orbital and three-quarters of one of the p orbitals. The new orbitals are called sp³ hybrid orbitals to show the proportions of the AOs in each. This process of mixing is called hybridization.

Combining four atomic orbitals on the same atom gives the same total number of hybrid orbitals. Each of these has one-quarter s character and three-quarters p character. The sp³ orbital has a planar node through the nucleus like a p orbital but one lobe is larger than the other because of the extra contribution of the 2s orbital, which adds to one lobe but subtracts from the other.

The four sp³ orbitals on one carbon atom point to the corners of a tetrahedron and methane can be formed by overlapping the large lobe of each sp³ orbital with
the 1s orbital of a hydrogen atom. Each overlap forms an MO \((2sp^3 + 1s)\) and we can put two elec-
trons in each to form a C–H \(\sigma\) bond. There will of course also be an antibonding MO, \(\sigma^*\) \((2sp^3 - 1s)\) in each case, but these orbitals are empty.

The great advantage of this method is that it can be used to build up structures of much larger
molecules quickly and without having to imagine that the molecule is made up from isolated atoms.
So it is easy to work out the structure of ethene (ethylene) the simplest alkene. Ethene is a planar
molecule with bond angles close to 120°. Our approach will be to hybridize all the orbitals needed
for the C–H framework and see what is left over. In this case we need three bonds from each carbon
atom (one to make a C–C bond and two to make C–H bonds).

Therefore we need to combine the 2s orbital on each carbon atom with two p orbitals to make the three bonds. We
could hybridize the 2s, 2p_x, and 2p_y orbitals (that is, all the AOs in the plane) to form three equal \(sp^2\) hybrid atomic
orbitals, leaving the 2p_z orbital unchanged. These \(sp^2\) hybrid orbitals will
have one-third s character and only two-
thirds p character.

The three \(sp^2\) hybrid atomic orbitals on
each carbon atom can overlap with three
other orbitals (two hydrogen 1s AOs and one \(sp^2\) AO from the other carbon) to form three \(\sigma\) MOs.
This leaves the two 2p_z orbitals, one on each carbon, which combine to form the \(\pi\) MO. The skeleton
of the molecule has five \(\sigma\) bonds (one C–C and four C–H) in the plane and the central \(\pi\) bond is
formed by two 2p_z orbitals above and below the plane.

Ethyne (acetylene) has a C–C triple bond. Each carbon bonds to only two other atoms to form a
linear CH skeleton. Only the carbon 2s and 2p_x have the right symmetry to bind to only two atoms at
once so we can hybridize these to form two sp hybrids on each carbon atom leaving the 2p_y and 2p_z
to form \(\pi\) MOs with the 2p orbitals on the other carbon atom. These sp hybrids have 50% each s and
p character and form a linear carbon skeleton.
We could then form the MOs as shown below. Each sp hybrid AO overlaps with either a hydrogen 1s AO or with the sp orbital from the other carbon. The two sets of p orbitals combine to give two mutually perpendicular π MOs.

Hydrocarbon skeletons are built up from tetrahedral (sp\(^3\)), trigonal planar (sp\(^2\)), or linear (sp) hybridized carbon atoms. It is not necessary for you to go through the hybridization process each time you want to work out the shape of a skeleton. In real life molecules are not made from their constituent atoms but from other molecules and it doesn’t matter how complicated a molecule might be or where it comes from; it will have an easily predictable shape. All you have to do is count up the single bonds at each carbon atom. If there are two, that carbon atom is linear (sp hybridized), if there are three, that carbon atom is trigonal (sp\(^2\) hybridized), and, if there are four, that carbon atom is tetrahedral (sp\(^3\) hybridized).

This hydrocarbon (hex-5-en-2-yne) has two linear sp carbon atoms (C\(_2\) and C\(_3\)), two trigonal sp\(^2\) carbon atoms (C\(_5\) and C\(_6\)), a tetrahedral sp\(^3\) CH\(_2\) group in the middle of the chain (C\(_4\)), and a tetrahedral sp\(^3\) methyl group (C\(_1\)) at the end of the chain. We had no need to look at any AOs to deduce this—we needed only to count the bonds.

If you had drawn the molecule more professionally as shown in the margin, you would have to check that you counted up to four bonds at each carbon. Of course, if you just look at the double and triple bonds, you will get the right answer without counting single bonds at all. Carbon atoms with no π bonds are tetrahedral (sp\(^3\) hybridized), those with one π bond are trigonal (sp\(^2\) hybridized), and those with two π bonds are linear (sp hybridized). This is essentially the VSEPR approach with a bit more logic behind it.

All normal compounds of carbon have eight electrons in the outer shell \((n = 2)\) of the carbon atom, all shared in bonds. It doesn’t matter where these electrons come from; just fit them into the right MOs on sp, sp\(^2\), or sp\(^3\) atoms.

We can hybridize any atoms

Hybridization is a property of AOs rather than specifically of carbon and, since all atoms have AOs, we can hybridize any atom. A tetrahedral arrangement of atoms about any central atom can be rationalized by describing the central atom as sp\(^3\) hybridized. The three molecules shown here all have a tetrahedral structure and in each case the central atom can be considered to be sp\(^3\) hybridized.

Each of these three molecules has four equivalent σ bonds from the central tetrahedral sp\(^3\) atom, whether this is B, C, or N, and the same total number of bonding electrons—the molecules are said to be isoelectronic. These three elements come one after the other in the periodic table so each nucleus has one more proton than the last: B has 5, C has 6, and N has 7. This is why the charge on the central atom varies.

Compounds of the same three elements with only three bonds are more complicated. Borane, BH\(_3\), has only three pairs of bonding electrons. The central boron atom bonds to only three other atoms. We can therefore describe it as being sp\(^2\) hybridized with an empty p orbital.

Each of the B–H bonds results from the overlap of an sp\(^2\) orbital with the hydrogen 1s orbital. The
The p orbital is not needed and contains no electrons. Do not be tempted by the alternative structure with tetrahedral boron and an empty sp³ orbital. You want to populate the lowest energy orbitals for greatest stability and sp² orbitals with their greater s character are lower in energy than sp³ orbitals. Another way to put this is that, if you have to have an empty orbital, it is better to have it of the highest possible energy since it has no electrons in it and doesn’t affect the stability of the molecule.

Borane is isoelectronic with the methyl cation, CH₃⁺. All the arguments we have just applied to borane also apply to Me⁺ so it too is sp² hybridized with a vacant p orbital. This will be very important when we discuss the reactions of carbocations in Chapter 17.

Now what about ammonia, NH₃? Ammonia is not isoelectronic with borane and Me⁺! As well as three N–H bonds, each with two electrons, the central nitrogen atom also has a lone pair of electrons. We have two choices: either we could hybridize the nitrogen atom sp² and put the lone pair in the p orbital or we could hybridize the nitrogen sp³ and have the lone pair in an sp³ orbital.

This is the opposite of the situation with borane and Me⁺. The extra pair of electrons does contribute to the energy of ammonia so it should be in the lower-energy orbital, sp³, rather than pure p. Experimentally the H–N–H bond angles are all 107.3°. Clearly, this is much closer to the 109.5° sp³ angle than to the 120° sp² angle. But the bond angles are not exactly 109.5°, so ammonia cannot be described as pure sp³ hybridized. VSEPR says the lone pair repels the bonds more than they repel each other. Alternatively, you could say that the orbital containing the lone pair must have slightly more s character while the N–H bonding orbitals must have correspondingly more p character.

The methyl anion, CH₃⁻, and hydronium ion, H₃O⁺, are both isoelectronic with ammonia so that all share the same pyramidal structure. Each is approximately tetrahedral with a lone pair in an sp³ orbital. These elements follow each other in the periodic table so the change in charge occurs because each nucleus has one more proton than the last. VSEPR also gives this answer.

**Shape of phosphine**

Phosphine, PH₃, has bond angles of about 90° and there is no need for hybridization. The three H 1s AO can overlap with the three 3p orbitals of the phosphorus atom, which leaves the lone pair in the 3s orbital. This 'pure s' lone pair is less energetic and therefore less reactive than the sp³ lone pair in ammonia which explains why ammonia is more basic than phosphine (see Chapter 8). In general atoms from Na to Ar are less likely to be hybridized than those from Li to Ne because the longer bonds mean the substituents are further from the central atom and steric interaction is less. VSEPR does not give this answer.

**Double bonds to other elements**

The C=O double bond is the most important functional group in organic chemistry. It is present in aldehydes, ketones, acids, esters, amides, and so on. We shall spend Chapters 5–10 discussing its chemistry so it is important that you understand its electronic structure. As in alkenes, the two atoms that make up this double bond are sp² hybridized. The carbon atom uses all three sp² orbitals for overlap with other orbitals to form σ bonds, but the oxygen uses only one for overlap with another orbital (the sp² orbitals on the carbon atom) to form a σ bond. However, the other two sp² orbitals are not vacant—they contain the oxygen’s two lone pairs. A π orbital from the carbon and one from the oxygen make up the π bond which also contains two electrons.
The less important double bonds to nitrogen (imines) are very similar but now there is only one lone pair on nitrogen and a second $\sigma$ bond to whatever substituent is on the nitrogen atom. Looking down on the planar structures of alkenes, imines, and ketones we see only the ends of the $p$ orbitals but the rest of the structures are clearly related.

*Alkenes* have a planar trigonal framework of $sp^2$ carbon atoms. Each uses one $sp^2$ orbital to form a $\sigma$ bond to the other carbon atom and two $sp^2$ orbitals to form $\sigma$ bonds to the substituents (here the general ‘R’). Two carbon $p$ orbitals are used for a $C$–$C$ $\pi$ bond. There are no lone pairs of electrons on either carbon atom.

*Imines* have a planar trigonal framework of an $sp^2$ carbon atom and an $sp^2$ nitrogen atom. Each uses one $sp^2$ orbital to form a $\sigma$ bond to the other atom and a $p$ orbital to form a $\pi$ bond to the other atom. The carbon uses two $sp^2$ orbitals and the nitrogen one to form $\sigma$ bonds to the substituents (here the general ‘R’). There is one lone pair of electrons on the nitrogen atom.

*Carbonyl compounds* have a planar trigonal framework of an $sp^2$ carbon atom and an $sp^2$ oxygen atom. Each uses one $sp^2$ orbital to form a $\sigma$ bond to the other atom and a $p$ orbital to form a $\pi$ bond to the other atom. The carbon uses two $sp^2$ orbitals to form $\sigma$ bonds to the substituents (here the general ‘R’). There are two lone pairs of electrons on the oxygen atom.

Where ‘R’ is joined to the double bond through a carbon atom, the nature of R determines which orbital will be used to pair up with the $sp^2$ orbital. In all the compounds shown below a saturated carbon atom with four bonds is joined to the double bond. The $C$–$C$ single bond is a $\sigma$ bond between
an sp² orbital on the ketone, imine, or alkene and an sp³ orbital on the substituent. It doesn’t make any difference that the second two compounds contain rings. In all cases the black bond joins a saturated, tetrahedral, sp³ carbon atom to the double bond and all the black σ bonds are between sp² and sp³ carbons or nitrogens.

All the other combinations are possible—here are just a few. It should be clear by now that σ bonds can form between any sort of orbitals that can point towards each other but that π bonds can form only between p orbitals.

Triple bonds can be formed between carbon and other elements too. The most important is the CN triple bond present in cyanides or nitriles. Both C and N are sp hybridized in these linear molecules, which leaves the lone pair on nitrogen in an sp orbital too. You will see (Chapter 8) how this affects the basicity of nitriles.

Conclusion

We have barely touched the enormous variety of molecules, but it is important that you realize at this point that these simple ideas of structural assembly can be applied to the most complicated molecules known. We shall use AOs and combine them into MOs to solve the structure of very small molecules and to deduce the structures of small parts of much larger molecules. With the additional ideas in Chapter 7 (conjugation) you will be able to grasp the structures of any organic compound. From now on we shall use terms like AO and MO, 2p orbital, sp² hybridization, σ bond, energy level, and populated orbital without further explanation. If you are unsure about any of them, refer back to this chapter for an explanation.

Problems

1. In the (notional and best avoided in practice) formation of NaCl from a sodium atom and a chlorine atom, descriptions like this abound in textbooks: ‘an electron is transferred from the valency shell of the sodium atom to the valency shell of the chlorine atom’. What is meant, in quantum number terms, by ‘valency shell’? Give a complete description in terms of all four quantum numbers of that transferred electron: (a) while it is in the sodium atom and (b) after it has been transferred to the chlorine atom. Why is the formation of NaCl by this process to be discouraged?
2. What is the electronic structure of these species? You should consult a periodic table before answering.

\[ \text{H}^0, \text{HS}^-, \text{K}^+, \text{Xe} \]

3. What sort of bonds can be formed between s orbitals and p orbitals? Which will provide better overlap, 1s + 2p or 1s + 3p? Which bonds will be stronger, those between hydrogen and C, N, O, and F on the one hand or those between hydrogen and Si, P, S, and Cl on the other? Within the first group, bond strength goes in this order: HF > OH > NH > CH. Why?

4. Though no helium ‘molecule’ He\(_2\) exists, an ion He\(_2^+\) does exist. Explain.

5. You may be surprised to know that the molecule CH\(_2\), with divalent carbon, can exist. It is of course very unstable but it is known and it can have two different structures. One has an H–C–H bond angle of 180° and the other an angle of 120°. Suggest structures for these species and say which orbitals will be occupied by all bonding and nonbonding electrons. Which structure is likely to be more stable?

6. Construct an MO diagram for the molecule LiH and suggest what type of bond it might have.

7. Deduce the MOs for the oxygen molecule. What is the bond order in oxygen and where are the 2p electrons?

8. Construct MOs for acetylene (ethyne) without hybridization.

9. What is the shape and hybridization of each carbon atom in these molecules?

10. Suggest detailed structures for these molecules and predict their shapes. We have deliberately made noncommittal drawings to avoid giving away the answer to the question. Don’t use these sorts of drawing in your answer.

\[ \text{CO}_2, \text{CH}_2=\text{NCH}_3, \text{CHF}_3, \text{CH}_2=\text{C}=\text{CH}_2, (\text{CH}_2)_2\text{O} \]
Chemical reactions

Most molecules are at peace with themselves. Bottles of water, or acetone (propanone, Me₂C=O), or methyl iodide (iodomethane CH₃I) can be stored for years without any change in the chemical composition of the molecules inside. Yet when we add chemical reagents, say, HCl to water, sodium cyanide (NaCN) to acetone, or sodium hydroxide to methyl iodide, chemical reactions occur. This chapter is an introduction to the reactivity of organic molecules: why they don’t and why they do react; how we can understand reactivity in terms of charges and orbitals and the movement of electrons; how we can represent the detailed movement of electrons—the mechanism of the reaction—by a special device called the curly arrow.

To understand organic chemistry you must be familiar with two languages. One, which we have concentrated on so far, is the structure and representation of molecules. The second is the description of the reaction mechanism in terms of curly arrows and that is what we are about to start. The first is static and the second dynamic. The creation of new molecules is the special concern of chemistry and an interest in the mechanism of chemical reactions is the special concern of organic chemistry.

Molecules react because they move. They move internally—we have seen (Chapter 3) how the stretching and bending of bonds can be detected by infrared spectroscopy. Whole molecules move continuously in space, bumping into each other, into the walls of the vessel they are in, and into the solvent if they are in solution. When one bond in a single molecule stretches too much it may break and a chemical reaction occurs. When two molecules bump into each other, they may combine with the formation of a new bond, and a chemical reaction occurs. We are first going to think about collisions between molecules.

Not all collisions between molecules lead to chemical change

All organic molecules have an outer layer of many electrons, which occupy filled orbitals, bonding and nonbonding. Charge–charge repulsion between these electrons ensures that all molecules repel each other. Reaction will occur only if the molecules are given enough energy (the activation energy for the reaction) for the molecules to pass the repulsion and get close enough to each other. If two molecules lack the required activation energy, they will simply collide, each bouncing off the electrons on the surface of the other and exchanging energy as they do so, but remain chemically...
unchanged. This is rather like a collision in snooker or pool. Both balls are unchanged afterwards but are moving in different directions at new velocities.

**Charge attraction brings molecules together**

In addition to this universal repulsive force, there are also important attractive forces between molecules if they are charged. Cations (+) and anions (−) attract each other electrostatically and this may be enough for reaction to occur. When an alkyl chloride, RCl, reacts with sodium iodide, NaI, in acetone (propanone, Me₂C=O) solution a precipitate of sodium chloride forms. Sodium ions, Na⁺, and chloride ions, Cl⁻, ions in solution are attracted by their charges and combine to form a crystalline lattice of alternating cations and anions—the precipitate of crystalline sodium chloride.

This inorganic style of attraction is rare in organic reactions. A more common cause of organic reactions is attraction between a charged reagent (cation or anion) and an organic compound that has a dipole. An example that we shall explore in this chapter is the reaction between sodium cyanide (a salt, NaCN) and a carbonyl compound such as acetone. Sodium cyanide is made up of sodium cations, Na⁺, and cyanide anions, CN⁻, in solution. Acetone has a carbonyl group, a C=O double bond, which is polarized because oxygen is more electronegative than carbon. The negative cyanide ion is attracted to the positive end of the carbonyl group dipole.

It is not even necessary for the reagent to be charged. Ammonia also reacts with acetone and this time it is the lone pair of electrons—a pair of electrons not involved in bonding and concentrated on the nitrogen atom of the uncharged ammonia molecule—that is attracted to the positive end of the carbonyl group dipole.

Polarity can arise from σ bonds too. The most electronegative element in the periodic table is fluorine and three fluorine atoms on electropositive boron produce a partially positively charged boron atom by σ bond polarization. The negative end of the acetone dipole (the oxygen atom) is attracted to the boron atom in BF₃.

But we have not told you the whole story about BF₃. Boron is in group 3 and thus has only six electrons around it in its trivalent compounds. A molecule of BF₃ is planar with an empty p orbital. This is the reverse of a lone pair. An empty orbital on an atom does not repel electron-rich areas of other molecules and so the oxygen atom of acetone is attracted electrostatically to the partial positive charge and one of the lone pairs on oxygen can form a bonding interaction with the empty orbital. We shall develop these ideas in the next section.
So, to summarize, the presence of a dipole in a molecule represents an imbalance in the distribution of the bonding electrons due to polarization of a $\sigma$ bond or a $\pi$ bond or to a pair of electrons or an empty orbital localized on one atom. When two molecules with complementary dipoles collide and together have the required activation energy to ensure that the collision is sufficiently energetic to overcome the general electronic repulsion, chemical change or reaction can occur.

**Orbital overlap brings molecules together**

Other organic reactions take place between completely uncharged molecules with no dipole moments. One of the old ‘tests’ for unsaturation was to treat the compound with bromine water. If the brown colour disappeared, the molecule was unsaturated. We don’t use ‘tests’ like these any more (spectroscopy means we don’t need to) but the reaction is still an important one. A simple symmetrical alkene combines with symmetrical bromine in a simple addition reaction.

The only electrons that might be useful in the kind of attraction we have discussed so far are the lone pair electrons on bromine. But we know from many experiments that electrons flow out of the alkene towards the bromine atom in this reaction—the reverse of what we should expect from electron distribution. The attraction between these molecules is not electrostatic. In fact, we know that reaction occurs because the bromine molecule has an empty orbital available to accept electrons. This is not a localized atomic orbital like that in the BF$_3$ molecule. It is the antibonding orbital belonging to the Br–Br $\sigma$ bond: the $\sigma^*$ orbital. There is therefore in this case an attractive interaction between a full orbital (the $\pi$ bond) and an empty orbital (the $\sigma^*$ orbital of the Br–Br bond). The molecules are attracted to each other because this one interaction is between an empty and a full orbital and leads to bonding, unlike all the other repulsive interactions between filled orbitals. We shall develop this less obvious attraction as the chapter proceeds.

Most organic reactions involve interactions between full and empty orbitals. Many also involve charge interactions, and some inorganic reactions involve nothing but charge attraction. Whatever the attraction between organic molecules, reactions involve electrons moving from one place to another. We call the details of this process the **mechanism of the reaction** and we need to explain some technical terms before discussing this.

**Electron flow is the key to reactivity**

The vast majority of organic reactions are polar in nature. That is to say, electrons flow from one molecule to another as the reaction proceeds. The electron donor is called a **nucleophile** (nucleus-loving) while the electron acceptor is called the **electrophile** (electron-loving). These terms come from the idea of charge attraction as a dominating force in reactions. The nucleophile likes nuclei because they are positively charged and the electrophile likes electrons because they are negatively charged. Though we no longer regard reactions as controlled only by charge interactions, these names have stuck.

Examples of reactions where the nucleophile is an anion and the electrophile is a cation and a new bond is formed simply by charge attraction leading to the combination of opposite charges include the reaction of sodium hydroxide with positively charged phosphorus compounds. The new bond between oxygen and phosphorus is formed by the donation of electrons from the nucleophile (hydroxide ion HO$^-$) to the electrophile (the positively charged phosphorus atom).
More often, reaction occurs when electrons are transferred from a lone pair to an empty orbital as in the reaction between an amine and BF$_3$. The amine is the nucleophile because of the lone pair of electrons on nitrogen and BF$_3$ is the electrophile because of the empty p orbital on boron.

The kind of bond formed in these two reactions used to be called a ‘dative covalent bond’ because both electrons in the bond were donated by the same atom. We no longer classify bonds in this way, but call them σ bonds or π bonds as these are the fundamentally different types of bonds in organic compounds. Most new bonds are formed by donation of both electrons from one atom to another.

These simple charge or orbital interactions may be enough to explain simple inorganic reactions but we shall also be concerned with nucleophiles that supply electrons out of bonds and electrophiles that accept electrons into antibonding orbitals. For the moment accept that polar reactions usually involve electrons flowing from a nucleophile and towards an electrophile.

### In reaction mechanisms

- Nucleophiles donate electrons
- Electrophiles accept electrons

Since we are describing a dynamic process of electron movement from one molecule to another in this last reaction, it is natural to use some sort of arrow to represent the process. Organic chemists use a curved arrow (called a ‘curly arrow’) to show what is going on. It is a simple and eloquent symbol for chemical reactions.

The curly arrow shows the movement of a pair of electrons from nitrogen into the gap between nitrogen and boron to form a new σ bond between those two atoms. This representation, what it means, and how it can be developed into a language of chemical reactions is our main concern in this chapter.

### Orbital overlap controls angle of successful attack

Electrostatic forces provide a generalized attraction between molecules in chemical reactions. In the reaction between chloride anions and sodium cations described above, the way in which these two spherical species approached one another was unimportant because the charges attracted one another from any angle. In most organic reactions the orbitals of the nucleophile and electrophile are directional and so the molecular orbitals of the reacting molecules exert important control. If a new bond is to be formed as the molecules collide, the orbitals of the two species must be correctly aligned in space. In our last example, only if the sp$^3$ orbital of the lone pair on nitrogen points directly at the empty orbital of the BF$_3$ can bond formation take place. Other collisions will not lead to reaction. In the first frame a successful collision takes place and a bond can be formed between the orbitals. In the second frame are three examples of unsuccessful collisions where no orbital overlap is possible. There are of course many more unproductive collisions but only one productive collision. Most collisions do not lead to reaction.
The orbitals must also have about the right amount of energy to interact profitably. Electrons are to be passed from a full to an empty orbital. Full orbitals naturally tend to be of lower energy than empty orbitals—that is after all why they are filled! So when the electrons move into an empty orbital they have to go up in energy and this is part of the activation energy for the reaction. If the energy gap is too big, few molecules will have enough energy to climb it and reaction will be bad. The ideal would be to have a pair of electrons in a filled orbital on the nucleophile and an empty orbital on the electrophile of the same energy. There would be no gap and reaction would be easy. In real life, a small gap is the best we can hope for.

Now we shall discuss a generalized example of a neutral nucleophile, Nu, with a lone pair donating its electrons to a cationic electrophile, E, with an empty orbital. Notice the difference between the curly arrow for electron movement and the straight reaction arrow. Notice also that the nucleophile has given away electrons so it has become positively charged and that the electrophile has accepted electrons so it has become neutral.

If we look at different possible relative energies for the lone pair orbital and the empty orbital, we might have equal energies, a small gap, or a large gap. Just as in Chapter 4, the horizontal lines represent energy levels, the arrows on them represent electrons, and the vertical scale is energy with high energy at the top and low energy at the bottom.

At first this picture suggests that the electrons will have to climb up to the empty orbital if it is higher in energy than the filled orbital. This is not quite true because, when atomic orbitals interact, their energies split to produce two new molecular orbitals, one above and one below the old orbitals. This is the basis for the static structure of molecules described in the last chapter and is also the key to reactivity. In these three cases this is what will happen when the orbitals interact (the new molecular orbitals are shown in black between the old atomic orbitals).
In each case there is actually a gain in energy when the electrons from the old lone pair drop down into the new stable bonding molecular orbital formed by the combination of the old atomic orbitals. The energy gain is greatest when the two orbitals are the same and least when they are very far apart in energy. The other new MO is higher in energy than either of the old AOs but it does not have to be occupied.

Only the highest-energy occupied orbitals of the nucleophile are likely to be similar in energy to only the lowest unoccupied orbitals of the electrophile. This means that the lower-lying completely filled bonding orbitals of the nucleophile can usually be neglected and only the highest occupied molecular orbital (HOMO) of the nucleophile and the lowest unoccupied molecular orbital (LUMO) of the electrophile are relevant. These may be of about the same energy and can then interact strongly. Orbital overlap—of both direction and energy—is therefore an important requirement for successful reaction between two organic molecules.

- Molecules repel each other because of their outer coatings of electrons. Molecules attract each other because of:
  - attraction of opposite charges
  - overlap of high-energy filled orbitals with low-energy empty orbitals

For reaction, molecules must approach each other so that they have:
- enough energy to overcome the repulsion
- the right orientation to use any attraction

We need now to look at which types of molecules are nucleophiles and which types are electrophiles. When you consider the reactivity of any molecule, this is the first question you should ask: is it nucleophilic or electrophilic?

**Nucleophiles donate high-energy electrons to electrophiles**

Nucleophiles are either negatively charged or neutral species with a pair of electrons in a high energy filled orbital that they can donate to electrophiles. The most common type of nucleophile has a nonbonding lone pair of electrons. Usually these are on a heteroatom such as O, N, S, or P.

These four neutral molecules, ammonia, water, trimethylphosphine, and dimethylsulfide, all have lone pairs of electrons in \( sp^3 \) orbitals and in each case this is the donor or nucleophilic orbital. The group VI atoms (O and S) have two lone pairs of equal energy. These are all nonbonding electrons and therefore higher in energy than any of the bonding electrons.
Anions are often nucleophiles too and these are also usually on heteroatoms such as O, S, or halogen which may have several lone pairs of equal energy. The first diagram for each of our examples shows the basic structure and the second diagram shows all the lone pairs. It is not possible to allocate the negative charge to a particular lone pair as they are the same.

There are a few examples of carbon nucleophiles with lone pairs of electrons, the most famous being the cyanide ion. Though linear cyanide has a lone pair on nitrogen and one on carbon, the nucleophilic atom is usually anionic carbon rather than neutral nitrogen as the sp orbital on carbon has a higher energy than that on the more electronegative nitrogen. Most anionic nucleophiles containing carbon have a heteroatom as the nucleophilic atom such as the anion methane thiolate shown above.

Neutral carbon electrophiles usually have a π bond as the nucleophilic portion of the molecule. When there are no lone pair electrons to supply high-energy nonbonding orbitals, the next best is the lower-energy filled π orbitals rather than the even lower-energy σ bonds. Simple alkenes are weakly nucleophilic and react with strong electrophilic species such as bromine. In Chapter 20 we shall see that the reaction starts by donation of the π electrons from the alkene into the σ* orbital of the bromine molecule (which breaks the Br–Br bond) shown here with a curly arrow. After more steps the dibromoalkane is formed but the molecules are attracted by overlap between the full π orbital and the empty σ* orbital.

It is possible for σ bonds to act as nucleophiles and we shall see later in this chapter that the borohydride anion, BH₄⁻, has a nucleophilic B–H bond and can donate those electrons into the π* orbital of a carbonyl compound breaking that bond and eventually giving an alcohol as product. The first stage of the reaction has electrons from the B–H single bond of nucleophilic anion BH₄⁻, which lacks lone pair electrons or π bonds, as the nucleophile.

In this section you have seen lone pairs on anions and neutral molecules acting as nucleophiles and, more rarely, π bonds and even σ bonds able to do the same job. In each case the nucleophilic electrons came from the HOMO—the highest occupied molecular orbital—of the molecule. Don’t worry if you find the curly arrows strange at the moment. They will soon be familiar. Now we need to look at the other side of the coin—the variety of electrophiles.

**Electrophiles have a low-energy vacant orbital**

Electrophiles are neutral or positively charged species with an empty atomic orbital (the opposite of a lone pair) or a low-energy antibonding orbital. The simplest electrophile is the proton, H⁺, a species without any electrons at all and a vacant 1s orbital. It is so reactive that it is hardly ever found and almost any nucleophile will react with it.

Each of the nucleophiles we saw in the previous section will react with the proton and we shall look at two of them together. Hydroxide ion combines with a proton to give water. This reaction is
governed by charge control. Then water itself reacts with the proton to give H$_3$O$^+$, the true acidic species in all aqueous strong acids.

We normally think of protons as acidic rather than electrophilic but an acid is just a special kind of electrophile. In the same way, Lewis acids such as BF$_3$ or AlCl$_3$ are electrophiles too. They have empty orbitals that are usually metallic p orbitals. We saw above how BF$_3$ reacted with Me$_3$N. In that reaction BF$_3$ was the electrophile and Me$_3$N the nucleophile. Lewis acids such as AlCl$_3$ react violently with water and the first step in this process is nucleophilic attack by water on the empty p orbital of the aluminium atom. Eventually alumina (Al$_2$O$_3$) is formed.

Few organic compounds have vacant atomic orbitals and most organic electrophiles have low-energy antibonding orbitals. The most important are $\pi^*$ orbitals as they are lower in energy than $\sigma^*$ orbitals and the carbonyl group (C=O) is the most important of these—indeed it is the most important functional group of all. It has a low-energy $\pi^*$ orbital ready to accept electrons and also a partial positive charge on the carbon atom. Previously we said that charge attraction helped nucleophiles to find the carbon atom of the carbonyl group.

Charge attraction is important in carbonyl reactions but so are the orbitals involved. Carbonyl compounds have a low-energy bonding $\pi$ orbital. Carbonyl compounds have a dipole because in this filled orbital the electrons are more on electronegative oxygen than on carbon. The same reason (electro-negative oxygen) makes this an exceptionally low-energy orbital and the carbonyl group a very stable structural unit. This orbital is rarely involved in reactions. Going up the energy scale we next have two degenerate (equal in energy) lone pairs in nonbonding orbitals. These are the highest-energy electrons in the molecule (HOMO) and are the ones that react with electrophiles.

When we consider the carbonyl group as an electrophile, we must look at antibonding orbitals too. The only one that concerns us is the relatively low-energy $\pi^*$ orbital of the C=O double bond (the LUMO). This orbital is biased towards the carbon to compensate for the opposite bias in the filled $\pi$ orbital. How do we know this if there are no electrons in it? Simply because nucleophiles, whether charged or not, attack carbonyl groups at the carbon atom. They get the best overlap with the larger orbital component of the $\pi^*$ orbital.

Protic and Lewis acids

Protic acids (also known as Brønsted acids) are electrophiles (like HCl) that can donate protons (H$^+$) to nucleophiles. They will be discussed in detail in Chapter 8. Lewis acids are also electrophiles but they donate more complicated cations to nucleophiles. They are usually metal halides such as LiCl, BF$_3$, AlCl$_3$, SnCl$_4$, and TiCl$_4$. We shall meet them in many later chapters, particularly in Chapters 22–8 when we discuss carbon–carbon bond formation.
So now we can draw a mechanism for the attack of a nucleophile on the carbonyl group. The lone pair electrons on the nucleophile move into the $\pi^*$ orbital of the C=O double bond and so break the $\pi$ bond, though not, of course, the $\sigma$ bond. Here is that process in curly arrow terms.

The lone pair electrons on oxygen interact better with empty orbitals such as the 1s of the proton and so carbonyl compounds are protonated on oxygen.

The resulting cation is even more electrophilic because of the positive charge but nucleophiles still attack the carbon atom of the carbonyl group because the $\pi^*$ orbital still has more contribution from carbon. The positive charge is neutralized even though the nucleophile does not attack the positively charged atom.

Even $\sigma$ bonds can be electrophilic if the atom at one end of them is sufficiently electronegative to pull down the energy of the $\sigma^*$ orbital. Familiar examples are acids where the acidic hydrogen atom is joined to strongly electronegative oxygen or a halogen thus providing a dipole moment and a relatively low-energy $\sigma^*$ orbital.

These two diagrams suggest two different ways of looking at the reaction between a base and an acid, but usually both interactions are important. Notice that an acid is just an electrophile that has an electrophilic hydrogen atom and a base is just a nucleophile that acts on a hydrogen atom. This question is explored more in Chapter 8. Bonds between carbon and halogen are also polarized in some cases though the electronegativity difference is sometimes very small.

It is easy to exaggerate the importance of single-bond polarization. The electronegativity difference between H and Cl is 0.9 but that...
between C and Br only 0.3 while the C–I bond is not polarized at all. When carbon–halogen σ bonds act as electrophiles, polarity hardly matters but a relatively low-energy σ* orbital is vitally important. The bond strength is also important in these reactions too as we shall see.

Some σ bonds are electrophilic even though they have no dipole at all. The halogens such as bromine (Br₂) are examples. Bromine is strongly electrophilic because it has a very weak Br–Br σ bond. Symmetrical bonds have the energies of the σ orbital and the σ* orbital roughly evenly distributed about the nonbonding level. A weak symmetrical σ bond means a small energy gap while a strong symmetrical σ bond means a large energy gap. Bromine is electrophilic but carbon–carbon σ bonds are not. Reverting to the language of Chapter 4, we could say that the hydrocarbon framework is made up of strong C–C bonds with low-energy populated and high-energy unpopulated orbitals, while the functional groups react because they have low LUMOs or high HOMOs.

An example would be the rapid reaction between a sulfide and bromine. No reaction at all occurs between a sulfide and ethane or any other simple C–C σ bond. Lone pair electrons are donated from sulfur into the Br–Br σ* orbital, which makes a new bond between S and Br and breaks the old Br–Br bond.

**Summary: interaction between HOMO and LUMO leads to reaction**

Organic reactions occur when the HOMO of a nucleophile overlaps with the LUMO of the electrophile to form a new bond. The two electrons in the HOMO slot into the empty LUMO. The reacting species may be initially drawn together by electrostatic interaction of charges or dipoles but this is not necessary. Thus at this simplest of levels molecular recognition is required for reaction. The two components of a reaction must be matched in terms of both charge–charge attraction and the energy and orientation of the orbitals involved.

Nucleophiles may donate electrons (in order of preference) from a lone pair, a π bond, or even a σ bond and electrophiles may accept electrons (again in order of preference) into an empty orbital or into the antibonding orbital of a π bond (π* orbital) or even a σ bond (σ* orbital). These antibonding orbitals are of low enough energy to react if the bond is very polarized by a large electronegativity difference between the atoms at its ends or, even for unpolarized bonds, if the bond is weak.

The hydrocarbon framework of organic molecules is unreactive. Functional groups such as NH₂ and OH are nucleophilic because they have nonbonding lone pairs. Carbonyl compounds and alkyl halides are electrophilic functional groups because they have low-energy LUMOs (π* for C=O and σ* for C–X, respectively).
Organic chemists use curly arrows to represent reaction mechanisms

You have seen several examples of curly arrows so far and you may already have a general idea of what they mean. The representation of organic reaction mechanisms by this means is so important that we must now make quite sure that you do indeed understand exactly what is meant by a curly arrow, how to use it, and how to interpret mechanistic diagrams as well as structural diagrams.

A curly arrow represents the actual movement of a pair of electrons from a filled orbital into an empty orbital. You can think of the curly arrow as representing a pair of electrons thrown, like a climber’s grappling hook, across from where he is standing to where he wants to go. In the simplest cases, the result of this movement is to form a bond between a nucleophile and an electrophile. Here are two examples we have already seen in which lone pair electrons are transferred to empty atomic orbitals.

Note the exact position of the curly arrow as the value of this representation lies in the precision and uniformity of its use. The arrow always starts with its tail on the source of the moving electrons, representing the filled orbital involved in the reaction. The head of the arrow indicates the final destination of the pair of electrons—the new bond between oxygen and hydrogen or oxygen and aluminium in these examples. As we are forming a new bond, the head of the arrow should be drawn to a point on the line between the two atoms.

When the nucleophile attacks an antibonding orbital, such as the weak Br–Br bond we have just been discussing, we shall need two arrows, one to make the new bond and one to break the old.

The bond-making arrow is the same as before but the bond-breaking arrow is new. This arrow shows that the two electrons in the bond move to one end (a bromine atom) and turn it into an anion. This arrow should start in the centre of the bond and its head should rest on the atom (Br in this case) at the end of the bond. Another example would be the attack of a base on the strong acid HBr.

It is not important how much curvature you put into the arrows or whether they are above or below the gaps of the bonds, both on the same side, or on opposite sides so long as they begin and end in the right places. All that matters is that someone who reads your arrows should be able to deduce exactly what is happening in the reaction from your arrows. We could have drawn the ammonia/HBr reaction like this if we had wished.

Charge is conserved in each step of a reaction

In all these examples we have reacted neutral molecules together to form charged species. Because the starting materials had no overall charge, neither must the products. If we start with neutral molecules and make a cation, we must make an anion too. Charge cannot be created or destroyed. If
our starting materials have an overall charge—plus or minus—then the same charge must appear in the products.

When it is a \( \pi \) bond that is being broken rather than a \( \sigma \) bond, only the \( \pi \) bond is broken and the \( \sigma \) bond should be left in place. This is what commonly happens when an electrophilic carbonyl group is attacked by a nucleophile. Just as in the breaking of a \( \sigma \) bond, start the arrow in the middle of the \( \pi \) bond and end by putting the arrowhead on the more electronegative atom, in this case oxygen rather than carbon.

In this case the starting materials had an overall negative charge and this is preserved as the oxyanion in the product. The charge disappears from the hydroxide ion because it is now sharing a pair of electrons with what was the carbonyl carbon atom and a charge appears on what was the carbonyl oxygen atom because it now has both of the electrons in the old \( \pi \) bond.

Electrons can be donated from \( \pi \) bonds and from \( \sigma \) bonds too. The reaction of an alkene with HBr is a simple example of a C–C \( \pi \) bond as nucleophile. The first arrow (on the nucleophile) starts in the middle of the \( \pi \) bond and goes into the gap between one of the carbon atoms and the hydrogen atom of HBr. The second arrow (on the electrophile) takes the electrons out of the H–Br \( \sigma \) bond and puts them on to the bromine atom to make bromide ion. This sort of reaction makes us place alkenes among the functional groups as well as part of the framework of organic molecules.

Notice that it was important to draw the two reagents in the right orientation since both are unsymmetrical and we want our arrow to show which end of the alkene reacts with which end of HBr. If we had drawn them differently we should have had trouble drawing the mechanism. Here is a less satisfactory representation.

If you find yourself making a drawing like this, it is worth having another go to see if you can be clearer. Drawing mechanisms is often rather experimental—try something and see how it looks: if it is unclear, try again. One way to avoid this particular problem is to draw an atom-specific curly arrow passing through the atom that reacts. Something like this will do.

This reaction does not, in fact, stop here as the two ions produced (charge conservation requires one cation and one anion in this first reaction) now react with each other to form the product of the reaction. This reaction is pretty obvious as the anion is the nucleophile and the cation, with its empty p orbital, is the electrophile.
The reaction that occurs between the alkene and HBr occurs in two stages—the formation of the ions and their combination. Many reactions are like this and we call the two stages steps so that we talk about 'the first step' and 'the second step', and we call the ions intermediates because they are formed in one step and disappear in the next. We shall discuss these intermediates in several later chapters (for example, 17 and 19).

When σ bonds act as nucleophiles, the electrons also have to go to one end of the σ bond as they form a new bond to the electrophile. We can return to an earlier example, the reaction of sodium borohydride (NaBH₄) with a carbonyl compound, and complete the mechanism. In this example, one of the atoms (the hydrogen atom) moves away from the rest of the BH₄ anion and becomes bonded to the carbonyl compound. The LUMO of the electrophile is, of course, the π* orbital of the C=O double bond.

The arrow on the nucleophile should again start in the middle of the bond that breaks and show which atom (the black H in this case) is transferred to the electrophile. The second arrow we have seen before. Here again you could use an atom-specific arrow to make it clear that the electrons in the σ bond act as a nucleophile through the hydrogen and not through the boron atom.

This reaction also occurs in two steps and the oxyanion is an intermediate, not a product. The reaction is normally carried out in water and the oxyanion reacts with water by proton transfer.

We shall discuss this reaction, the reduction of carbonyl compounds by NaBH₄, in detail in Chapter 6.

The decomposition of molecules

So far we have described reactions involving the combination of one molecule with another. Many reactions are not like this but involve the spontaneous decomposition of one molecule by itself without any assistance from any other molecule. In these reactions there is no electrophile or nucleophile. The usual style of reaction consists of a weak, often polarized σ bond breaking to give two new molecules or ions. The dissociation of a strong acid HX is a simple example.

In organic chemistry spontaneous dissociation of diazonium salts, compounds containing the N₂⁺ group, occurs very easily because one of the products, nitrogen gas (‘dinitrogen’) is very stable. It does not much matter what R is (alkyl or aryl); this reaction happens spontaneously at room temperature.

This is not, of course, the end of the reaction as R⁺ is very reactive and we shall see the sort of things it can do in Chapters 17 and 19. More commonly, some sort of catalysis is involved in decomposition reactions. An important example is the decomposition of tertiary alcohols in acid solution. The carbon–oxygen bond of the alcohol does not break by itself but, after the oxygen atom has been protonated by the acid, decomposition occurs.

This two-step mechanism is not finished because the positive ion (one particular example of R⁺) reacts further (Chapter 17). In the decomposition step the positive charge on the oxygen atom as well as the fact that the other product is water helps to break the strong C–O σ bond. In these three
examples, the functional group that makes off with the electrons of the old σ bond (X, N\(^{2+}\), and OH\(^{2+}\)) is called the leaving group, and we shall be using this term throughout the book. The spontaneous decomposition of molecules is one of the clearest demonstrations that curly arrows mean the movement of two electrons. Chemical reactions are dynamic processes, molecules really do move, and electrons really do leave one atomic or molecular orbital to form another.

These three examples all have the leaving group taking both electrons from the old σ bond. This type of decomposition is sometimes called heterolytic fission or simply heterolysis and is the most common in organic chemistry. There is another way that a σ bond can break. Rather than a pair of electrons moving to one of the atoms, one electron can go in either direction. This is known as homolytic fission as two species of the same charge (neutral) will be formed. It normally occurs when similar or indeed identical atoms are at each end of the σ bond to be broken. Both fragments have an unpaired electron and are known as radicals. This type of reaction occurs when bromine gas is subjected to sunlight.

The weak Br–Br bond breaks to form two bromine radicals. This can be represented by two single-headed curly arrows, fish hooks, to indicate that only one electron is moving. This is virtually all you will see of this special type of curly arrow until we consider the reactions of radicals in more detail (Chapter 39). When you meet a new reaction you should assume that it is an ionic reaction and use two-electron arrows unless you have a good reason to suppose otherwise.

Curly arrows also show movement of electrons within molecules

So far all the mechanisms we have drawn have used only one or two arrows in each step. In fact, there is no limit to the number of arrows that might be involved and we need to look at some mechanisms with three arrows. The third arrow in such mechanisms usually represents movement of electrons inside of the reacting molecules. Some pages back we drew out the addition of a nucleophile to a carbonyl compound.

This is a two-arrow mechanism but, if we lengthen the structure of the carbonyl compound by adding a double bond in the right position, we can add the nucleophile to a different position in the molecule by moving electrons within the molecule using a third arrow.

The first arrow from the nucleophile makes a new σ bond and the last breaks the carbonyl π bond. The middle arrow just moves the C–C π bond along the molecule. If you inspect the product you will see that its structure follows precisely from the arrows. The middle arrow starts in the middle of a π bond and ends in the middle of a σ bond. All it does is to move the π electrons along the molecule. It turns the old π bond into a σ bond and the old σ bond into a π bond. We shall discuss this sort of reaction in Chapter 10.

In some mechanisms there is a second step in the mechanism and both are three-arrow processes. Here is the first step in such a mechanism. See if you can understand each arrow before reading the explanation in the next paragraph.

The arrow from the hydroxide ion removes a proton from the molecule making a new O–H bond in a molecule of water. The middle arrow moves the electrons of a C–H bond into a C–C bond making it into a π bond and the third arrow polarizes the carbonyl π bond leaving an oxyanion as the product. Charge is conserved—an anion gives an anion. In fact this ‘product’ is only an intermediate and the second step also involves three arrows.
Starting from the oxyanion, the first arrow re-forms the carbonyl group, the middle arrow moves a π bond along the molecule, and the third arrow breaks a C–O σ bond releasing hydroxide ion as one of the products of the reaction. We shall meet this sort of reaction in detail later (Chapters 19 and 27).

Mostly for entertainment value we shall end this section with a mechanism involving no fewer than eight arrows. See if you can draw the product of this reaction without looking at the result.

The first arrow forms a new C–S σ bond and the last arrow breaks a C–Br σ bond but all the rest just move π bonds along the molecule. The product is therefore:

We shall not be discussing this reaction anywhere in the book! We have included it just to convince you that, once you understand the principle of curly arrows, you can understand even very complicated mechanisms quite easily. At this stage we can summarize the things you have learned about interpreting a mechanism drawn by someone else.

Summary: what do curly arrows mean?

- A curly arrow shows the movement of a pair of electrons
- The tail of the arrow shows the source of the electron pair, which will be a filled orbital (HOMO) such as a lone pair or a π bond or a σ bond
- The head of the arrow indicates the ultimate destination of the electron pair which will either be:
  - an electronegative atom that can support a negative charge (a leaving group)
  - or an empty orbital (LUMO) when a new bond will be formed
  - or an antibonding orbital (π* or σ*) when that bond will break
- Overall charge is always conserved in a reaction. Check that your product obeys this rule

Now would be a good time to do Problems 1 and 2 at the end of the chapter, which will give you practice in the interpretation of mechanisms.

Drawing your own mechanisms with curly arrows

Curly arrows must be drawn carefully! The main thing you need to remember is that curly arrows must start where there is a pair of electrons and end somewhere where you can leave a pair of electrons without drawing an absurd structure. That sounds very simple—and it is—but you need some practice to see what it means in detail in different circumstances. Let us look at the implications with a reaction whose products are given: the reaction of triphenylphosphine with methyl iodide.

First observe what has happened: a new bond has been formed between the phosphorus atom and the methyl group and the carbon–iodine bond has been broken. Arrows represent movement of electron pairs not atoms so the reactants must be drawn within bonding distance before the mechanism can be drawn. This is analogous to the requirement that molecules must collide before they can react. First draw the two molecules so that the atoms that form the new bond (P and C) are near each other and draw out the bonds that are involved (that is, replace ‘MeI’ with a proper chemical structure).

Now ask: which is the electrophile and which the nucleophile (and why)? The phosphorus atom has a lone pair and the carbon atom does not so Ph₃P must be the nucleophile and the C–I bond of MeI must be the electrophile. All that remains is to draw the arrows.

Admittedly, that was quite an easy mechanism to draw but you should still be pleased if you succeeded at your first try.
Warning! Eight electrons is the maximum for B, C, N, or O

We now ought to spell out one thing that we have never stated but rather assumed. Most organic atoms, if they are not positively charged, have their full complement of electrons (two in the case of hydrogen, eight in the cases of carbon, nitrogen, and oxygen) and so, if you make a new bond to one of those elements, you must also break an existing bond. Suppose you just ‘added’ Ph3P to MeI in this last example without breaking the C–I bond: what would happen?

This structure must be wrong because carbon cannot have five bonds—if it did it would have ten electrons in the 2s and the 2p orbitals. As there are only four of those (2s, 2p_x, 2p_y, and 2p_z) and they can have only two electrons each, eight electrons is the maximum and that means that four bonds is the maximum.

If you make a new bond to uncharged H, C, N, or O you must also break one of the existing bonds in the same step.

There is a nasty trap when a charged atom has its full complement of electrons. Since BH\textsubscript{4} and NH\textsubscript{4}\textsuperscript{+} are isoelectronic with methane and have four \( \sigma \) bonds and hence eight electrons, no new bonds can be made to B or N. The following attractive mechanisms are impossible because boron has no lone pair in BH\textsubscript{4} and nitrogen has no empty orbital in NH\textsubscript{4}\textsuperscript{+}.

Reactions with BH\textsubscript{4} always involve the loss of H and a pair of electrons using the BH bond as nucleophile and reactions with NH\textsubscript{4}\textsuperscript{+} always involve the loss of H without a pair of electrons using the NH bond as electrophile.

Similarly, nucleophiles do not attack species like H\textsubscript{3}O\textsuperscript{+} at oxygen, even though it is the oxygen atom that carries the positive charge. Reaction occurs at one of the protons, which also neutralizes the positive charge. Or, to put it another way, H\textsubscript{3}O\textsuperscript{+} is an acid (electrophilic at hydrogen) and not electrophilic at oxygen.

Try a simple example: primary alcohols can be converted into symmetrical ethers in acid solution. Suggest a mechanism for this acid-catalysed conversion of one functional group into another.
The reaction must start by the protonation of something and the only candidate is the oxygen atom as it alone has lone pair electrons. This gives us a typical oxonium ion with three bonds to oxygen and a full outer shell of eight electrons.

To make the ether a second molecule of alcohol must be added but we must not now be tempted to attack the positively charged oxygen atom with the nucleophilic OH group. The second molecule could attack a proton, but that would just make the same molecules. Instead it must attack at carbon expelling a molecule of water as a leaving group and creating a new oxonium ion.

Finally, the loss of the proton from the new oxonium ion gives the ether. Though this is a three-step mechanism, two of the steps are just proton transfers in acidic solution and the only interesting step is the middle one. Here is the whole mechanism.

Drawing a two-step mechanism: cyanohydrin formation

Now what about this slightly more complicated example? Sodium cyanide is added to a simple aldehyde in aqueous solution. The product is a cyanohydrin and we shall discuss this chemistry in Chapter 6.

This reaction is presented in a style with which you will become familiar. The organic starting material is written first and then the reagent over the reaction arrow and the solvent under it. We must decide what happens. NaCN is an ionic solid so the true reagent must be cyanide ion. As it is an anion, it must be the nucleophile and the carbonyl group must be the electrophile. Let us try a mechanism.

This is a good mechanism but it doesn’t quite produce the product. There must be a second step in which the oxyanion picks up a proton from somewhere. The only source of protons is the solvent, water, so we can write:

This is the complete mechanism and we can even make a prediction about the reaction conditions from it. The second step needs a proton and water is not a very good proton donor. A weak acid as catalyst would help.

Now for a real test: can you draw a mechanism for this reaction?

You might well protest that you don’t know anything about the chemistry of three-membered rings or of either of the functional groups, SH and cyclic ether. Be that as it may, you can still draw a mechanism for the reaction. It is important that you are prepared to try your hand at mechanisms for new reactions as you can learn a lot this way. Ask first of all: which bonds have been formed and which broken? Clearly the S–H bond has been broken and a new S–C bond formed. The three-membered ring has gone by the cleavage of one of the C–O bonds. The main chain of carbon atoms is unchanged. We might show these ideas in some way such as this.
Now you could continue in many ways. You might say ‘what breaks the SH bond?’ This must be the role of the base as a base removes protons. You might realize that the reaction cannot happen while the sulfur atom is so far away from the three-membered ring (no chance of a collision) and redraw the molecule so that the reaction can happen.

Now draw the mechanism. It is easy once you have done the preparatory thinking. The sulfur anion must be the nucleophile so the C–O bond in the three-membered ring must be the electrophile. Here goes!

That is not quite the product so we must add a proton to the oxyanion. Where can the proton come from? It must be the proton originally removed by the base as there is no other. We can write B for the base and hence BH⁺ for the base after it has captured a proton.

Your mechanism probably didn’t look as neat as the printed version but, if you got it roughly right, you should be proud. This is a three-step mechanism involving chemistry unknown to you and yet you could draw a mechanism for it. Are you using coloured arrows, by the way? We are using black arrows on red diagrams but the only point of that is to make the arrows stand out. We suggest you use any colour for your arrows that contrasts with your normal ink.

**Decide on a ‘push’ or a ‘pull’ mechanism**

In one step of a reaction mechanism electrons flow from a site rich in electrons to an electron-deficient site. When you draw a mechanism you must make sure that the electrons flow in one direction only and neither meet at a point nor diverge from a point. One way to do this is to decide whether the mechanism is ‘pushed’ by, say, a lone pair or an anion or whether it is ‘pulled’ by, say, a cation, an empty orbital, or by the breaking of a reactive weak π bond or σ bond. This is not just a device either. Extremely reactive molecules, such as fluorine gas, F₂, react with almost anything—in this case because of the very electrophilic F–F σ bond (low energy F–F σ⁺ orbital). Reactions of F₂ are ‘pulled’ by the breaking of the F–F bond. The nearest thing in organic chemistry is probably the reactions of carbon cations such as those formed by the decomposition of diazonium salts.

In the first step the electrons of the σ bond are pulled away by the positive charge and the very stable leaving group, N₂. In the second step lone pair electrons are pulled into the very reactive cation by the nonbonding empty orbital on carbon. Even very weak nucleophiles such as water will react with such cations as a real example shows.

In all our previous examples we have drawn the first arrow from the nucleophile, anion, lone pair, or whatever and pushed the electrons along the chain of arrows. This is a natural thing to do; indeed the skill of drawing mechanisms is sometimes derisively referred to as ‘electron pushing’, but some mechanisms are more easily understood as ‘electron pulling’. In general, if a cation, an acid, or a Lewis acid is a reagent or a catalyst, the reaction is probably pulled. If an anion or a base is involved as a reagent, the reaction is probably pushed. In any case it isn’t so important which approach you adopt as that you should do one or the other and not muddle them up.
A more interesting example of a pull mechanism is the reaction of isoprene (2-methylbutadiene) with HBr. The product is an unsaturated alkyl bromide (a bromoalkene).

What has happened? HBr has clearly added to the diene while one of the double bonds has vanished. However, the remaining double bond, whichever it is, has moved to a new position in the middle of the molecule. So how do we start? HBr is a strong acid so the reaction must begin with the protonation of some atom in the diene by HBr. Which one? If you examine the product you will see that one atom has an extra hydrogen and this must be where protonation occurs.

The only change is at the left-hand end of the molecule where there is an extra proton. We must add the proton of HBr to that atom. The highest-energy orbital at that atom is the rather unreactive alkene π bond so we must use that as the nucleophile, though the electrons are really being pulled out of the π bond by reactive HBr.

It is not necessary to draw in that hydrogen atom in the product of this step. It is, of course, necessary to put the positive charge on the carbon atom in the middle that has lost electrons. Now we can add bromide ion (the other product of the first step) to this cation but not where we have written the plus charge as that will not give us the right product. We must move the remaining double bond along the molecule as we add the bromide ion. This too is a ‘pulled’ reaction as the unstable plus charge on carbon pulls electrons towards itself.

So this is a two-step reaction and the driving force for the two steps is a strongly acidic electrophile in the first and a strongly electrophilic cation at carbon in the second. Here is the full mechanism.

Now we can summarize the extra points we have made in this section as a series of guidelines.

**Extra guidelines for writing your own mechanisms**

- Decide on the structure of any ambiguous reagents, for example, salt or a covalent compound?
- Decide which is the nucleophilic and which the electrophilic atom
- Decide whether to think in a *push* or a *pull* manner
- Mark lone pairs on the nucleophilic atom
- Draw the molecule(s) in a spatial arrangement that makes reaction possible
- Curly arrows always move in the same direction. They never meet head on!
- If you make a new bond to H, C, N, or O you must also break one of the existing bonds in the same step
- Draw your arrows in colour to make them stand out
- Mark charges clearly on reactants and intermediates
- Make sure that overall charge is conserved in your mechanism

We have only given you a preliminary trial run as a learner driver of curly arrows in this section. The way forward is practice, practice, practice.
Curly arrows are vital for learning organic chemistry

Curly arrows can be used to explain the interaction between the structure of reactants and products and their reactivity in the vast majority of organic reactions, regardless of their complexity. When used correctly they can even be used to predict possible outcomes of unknown processes and hence to design new synthetic reactions. They are thus a powerful tool for understanding and developing organic chemistry and it is vital that you become proficient in their use. They are the dynamic language of organic reaction mechanisms and they will appear in every chapter of the book from now on.

Another equally important reason for mastering curly arrows now, before you start the systematic study of different types of reactions, is that the vast number of ‘different reactions’ turn out not to be so different after all. Most organic reactions are ionic; they therefore all involve nucleophiles and electrophiles and two-electron arrows. There are relatively few types of organic electrophiles and nucleophiles and they are involved in all the ‘different’ reactions. If you understand and can draw mechanisms, the similarity between seemingly unrelated reactions will become immediately apparent and thus the number of distinct reaction types is dramatically reduced.

Drawing curly arrow mechanisms is a bit like riding a bike. Before you’ve mastered the skill, you keep falling off. Once you’ve mastered the skill, it seems so straightforward that you wonder how you ever did without it. You still come across busy streets and complex traffic junctions, but the basic skill remains the same.

If you still feel that drawing mechanisms for yourself is difficult, this stage-by-stage guide may help you. Once you’ve got the idea, you probably won’t need to follow it through in detail.

A guide to drawing mechanisms with curly arrows

1. Draw out the reagents as clear structures following the guidelines in Chapter 2. Check that you understand what the reagents and the solvent are under the conditions of the reaction, for example, if the reaction is in a base, will one of the compounds exist as an anion?

2. Inspect the starting materials and the products and assess what has happened in the reaction. What new bonds have been formed? What bonds have been broken? Has anything been added or removed? Have any bonds moved around the molecule?

3. Identify the nucleophilic centres in all the reactant molecules and decide which is the most nucleophilic. Then identify the electrophiles present and again decide which is the most electrophilic.

4. If the combination of these two centres appears to lead to the product, draw the reactants, complete with charges, so as to position the nucleophilic and electrophilic centres within bonding distance ensuring that the angle of attack of the nucleophile is more or less consistent with the orbitals involved.

5. Draw a curly arrow from the nucleophile to the electrophile. It must start on the filled orbital or negative charge (show this clearly by just touching the bond or charge) and finish on the empty orbital (show this clearly by the position of the head). You may consider a ‘push’ or a ‘pull’ mechanism at this stage.

6. Consider whether any atom that has been changed now has too many bonds; if so one of them must be broken to avoid a ridiculous structure. Select a bond to break. Draw a curly arrow from the centre of the chosen bond, the filled orbital, and terminate it in a suitable place.

7. Write out the structures of the products specified by the curly arrows. Break the bonds that are the sources of the arrows and make those that are the targets. Consider the effect on the charges on individual atoms and check that the overall charge is not changed. Once you have drawn the curly arrows, the structure of the products is already decided and there is no room for any further decisions. Just write what the curly arrows tell you. If the structure is wrong, then the curly arrows were wrong so go back and change them.

8. Repeat stages 5–7 as required to produce a stable product.
When you have read through all the different types of reaction mechanism, practise drawing them out with and without the help of the book. Complete the exercises at the end of the chapter and then try to devise mechanisms for other reactions that you may know. You now have the tools to draw out in the universal pictorial language of organic chemists virtually all the mechanisms for the reactions you will meet in this book and more besides!

**Problems**

1. Each of these molecules is electrophilic. Identify the electrophilic atom and draw a mechanism for reaction with a generalized nucleophile Nu–, giving the product in each case.

![Chemical structures](image.png)

2. Each of these molecules is nucleophilic. Identify the electrophilic atom and draw a mechanism for reaction with a generalized electrophile E+, giving the product in each case.

![Chemical structures](image.png)

3. Complete these mechanisms by drawing the structure of the products in each case.

![Mechanism 1](image.png)

![Mechanism 2](image.png)

4. Each of these electrophiles could react with a nucleophile at (at least) two different atoms. Identify these atoms and draw a mechanism for each reaction together with the products from each.

![Chemical structures](image.png)

5. Put in the arrows on these structures (which have been drawn with all the atoms in the right places!) to give the products shown.

![Chemical structures](image.png)

6. Draw mechanisms for these reactions. The starting materials have not necessarily been drawn in a helpful way.

![Mechanism 3](image.png)

![Mechanism 4](image.png)

7. Draw a mechanism for this reaction.

\[
\text{PhCHBr.CHBr.CO}_2\text{H} + \text{NaHCO}_3 \rightarrow \text{PhCH=CHBr}
\]

*Hints.* First draw good diagrams of the reagents. NaHCO₃ is a salt and a weak base—strong enough only to remove which proton? Then work out which bonds are formed and which broken, decide whether to push or pull, and draw the arrows. What are the other products?
Molecular orbitals explain the reactivity of the carbonyl group

We are now going to leave to one side most of the reactions you met in the last chapter—we will come back to them all again later in the book. In this chapter we are going to concentrate on just one of them—probably the simplest of all organic reactions—the addition of a nucleophile to a carbonyl group. The carbonyl group, as found in aldehydes, ketones, and many other compounds, is without doubt the most important functional group in organic chemistry, and that is another reason why we have chosen it as our first topic for more detailed study.

You met nucleophilic addition to a carbonyl group on p. 114 and 119, where we showed you how cyanide reacts with acetone to give an alcohol. As a reminder, here is the reaction again, with its mechanism.

![Reaction Scheme]

The reaction has two steps: nucleophilic addition of cyanide, followed by protonation of the anion. In fact, this is a general feature of all nucleophilic additions to carbonyl groups.

- Additions to carbonyl groups generally consist of two mechanistic steps:
  1. Nucleophilic attack on the carbonyl group
  2. Protonation of the anion that results

The addition step is more important, and it forms a new C–C σ bond at the expense of the C=O π bond. The protonation step makes the overall reaction addition of HCN across the C=O π bond.
Why does cyanide, in common with many other nucleophiles, attack the carbonyl group? And why does it attack the carbon atom of the carbonyl group? To answer these questions we need to look in detail at the structure of carbonyl compounds in general and the orbitals of the C=O group in particular.

The carbonyl double bond, like that found in alkenes (whose bonding we discussed in Chapter 4), consists of two parts: one σ bond and one π bond. The σ bond between the two sp² hybridized atoms—carbon and oxygen—is formed from two sp² orbitals. The other sp² orbitals on carbon form the two σ bonds to the substituents while those on oxygen are filled by the two lone pairs. The sp² hybridization means that the carbonyl group has to be planar, and the angle between the substituents is close to 120°. The diagram illustrates all this for the simplest carbonyl compound, formaldehyde (or methanal, CH₂O). The π bond then results from overlap of the remaining p orbitals—again, you can see this for formaldehyde in the diagram.

Notice that we have drawn the π bond skewed towards oxygen. This is because oxygen is more electronegative than carbon, polarizing the orbital as shown. Conversely, the unfilled π* antibonding orbital is skewed in the opposite direction, with a larger coefficient at the carbon atom. Put all of this together and we get the complete picture of the orbitals of a carbonyl group.

Electronegativities, bond lengths, and bond strengths

Because there are two types of bonding between C and O, the C=O double bond is rather shorter than a typical C–O single bond, and also over twice as strong—so why is it so reactive? Polarization is the key. The polarized C=O bond gives the carbon atom some degree of positive charge, and this charge attracts negatively charged nucleophiles (like cyanide) and encourages reaction. The polarization of the antibonding π* orbital towards carbon is also important, because, when the carbonyl group reacts with a nucleophile, electrons move from the HOMO of the nucleophile (an sp orbital in this case) into the LUMO of the electrophile—in other words the π* orbital of the C=O bond. The greater coefficient of the π* orbital at carbon means a better HOMO–LUMO interaction, so this is where the nucleophile attacks.

As our nucleophile—which we are representing here as ‘Nu’—approaches the carbon atom, the electron pair in its HOMO starts to interact with the LUMO (antibonding π*) to form a new σ bond.
Filling antibonding orbitals breaks bonds and, as the electrons enter the antibonding $\pi^*$ of the carbonyl group, the $\pi$ bond is broken, leaving only the C–O $\sigma$ bond intact. But electrons can’t just vanish, and those that were in the $\pi$ bond move off on to the electronegative oxygen, which ends up with the negative charge that started on the nucleophile. You can see all this happening in the diagram below.

Notice how the trigonal, planar $sp^2$ hybridized carbon atom of the carbonyl group changes to a tetrahedral, $sp^3$ hybridized state in the product. For each class of nucleophile you meet in this chapter, we will show you the HOMO–LUMO interaction involved in the addition reaction.

**Cyanohydrins from the attack of cyanide on aldehydes and ketones**

Now that we’ve looked at the theory of how a nucleophile attacks a carbonyl group, let’s go back to the real reaction with which we started this chapter: cyanohydrin formation from a carbonyl compound and sodium cyanide. Cyanide contains $sp$ hybridized C and N atoms, and its HOMO is an $sp$ orbital on carbon. The reaction is a typical nucleophilic addition reaction to a carbonyl group: the electron pair from the HOMO of the CN$^-$ (an $sp$ orbital on carbon) moves into the C=O $\pi^*$ orbital; the electrons from the C=O $\pi$ orbital move on to the oxygen atom. The reaction is usually carried out in the presence of acid, which protonates the resulting alkoxide to give the hydroxyl group of the composite functional group known as a cyanohydrin. The reaction works with both ketones and aldehydes, and the mechanism below shows the reaction of a general aldehyde.
Cyanohydrins are important synthetic intermediates — for example, the cyanohydrin formed from this cyclic amino ketone forms the first step of a synthesis of some medicinal compounds known as 5HT₃ agonists, which were designed to reduce nausea in chemotherapy patients. Cyanohydrins are also components of many natural and industrial products, such as the insecticides cypermethrin (marketed as ‘Ripcord’, ‘Barricade’, and ‘Imperator’) and fluvalinate.

Cyanohydrin formation is reversible: just dissolving a cyanohydrin in water can give back the aldehyde or ketone you started with, and aqueous base usually decomposes cyanohydrins completely.

Cyanohydrin formation is therefore an equilibrium between starting materials and products, and we can only get good yields if the equilibrium favours the products. The equilibrium is more favourable for aldehyde cyanohydrins than for ketone cyanohydrins, and the reason is the size of the groups attached.

Some equilibrium constants

Cyanohydrins and cassava

The reversibility of cyanohydrin formation is of more than theoretical interest. In parts of Africa the staple food is cassava. This food contains substantial quantities of the glucoside of acetone cyanohydrin (a glucoside is an acetal derived from glucose). We shall discuss the structure of glucose later in this chapter, but for now, just accept that it stabilizes the cyanohydrin.

The glucoside is not poisonous in itself, but enzymes in the human gut break it down and release HCN. Eventually 50 mg HCN per 100 g of cassava can be released and this is enough to kill a human being after a meal of unfermented cassava. If the cassava is crushed with water and allowed to stand (‘ferment’), enzymes in the cassava will do the same job and then the HCN can be washed out before the cassava is cooked and eaten. The cassava is now safe to eat but it still contains some glucoside. Some diseases found in eastern Nigeria can be traced to long-term consumption of HCN. Similar glucosides are found in apple pips and the kernels inside the stones of fruit such as peaches and apricots. Some people like eating these, but it is unwise to eat too many at one sitting!
to the carbonyl carbon atom. As the carbonyl carbon atom changes from sp² to sp³, its bond angles change from about 120° to about 109°—in other words, the substituents it carries move closer together. This reduction in bond angle is not a problem for aldehydes, because one of the substituents is just a (very small) hydrogen atom, but for ketones, especially ones that carry larger alkyl groups, this effect can disfavour the addition reaction. Effects that result from the size of substituents and the repulsion between them are called steric effects, and we call the repulsive force experienced by large substituents steric hindrance.

The angle of nucleophilic attack on aldehydes and ketones

Having introduced you to the sequence of events that makes up a nucleophilic attack at C=O (interaction of HOMO with LUMO, formation of new σ bond, breakage of π bond), we should now tell you a little more about the direction from which the nucleophile approaches the carbonyl group. Not only do nucleophiles always attack carbonyl groups at carbon, but they also always approach from a particular angle. You may at first be surprised by this angle, since nucleophiles attack not from a direction perpendicular to the plane of the carbonyl group but at about 107° to the C=O bond. This approach route is known as the Bürgi–Dunitz trajectory after the authors of the elegant crystallographic methods that revealed it. You can think of the angle of attack as the result of a compromise between maximum orbital overlap of the HOMO with π* and minimum repulsion of the HOMO by the electron density in the carbonyl π bond.

Any other portions of the molecule that get in the way of (or, in other words, that cause steric hindrance to) the Bürgi–Dunitz trajectory will greatly reduce the rate of addition and this is another reason why aldehydes are more reactive than ketones. The importance of the Bürgi–Dunitz trajectory will become more evident later—particularly in Chapter 34.

Nucleophilic attack by ‘hydride’ on aldehydes and ketones

Nucleophilic attack by the hydride ion, H⁻, is not a known reaction. This species, which is present in the salt sodium hydride, NaH, is so small and has such a high charge density that it only ever reacts as a base. The reason is that its filled 1s orbital is of an ideal size to interact with the hydrogen
atom’s contribution to the $\sigma^*$ orbital of an H–X bond (X can be any atom), but much too small to interact easily with carbon’s more diffuse 2p orbital contribution to the LUMO ($\pi^*$) of the C=O group.

Nevertheless, adding H– to the carbon atom of a C=O group would be a very useful reaction, as the result would be the formation of an alcohol. This process would involve going down from the aldehyde or ketone oxidation level to the alcohol oxidation level (Chapter 2, pp. 25–36) and would therefore be a reduction. It cannot be done with NaH, but it can be done with some other compounds containing nucleophilic hydrogen atoms.

The most important of these compounds is sodium borohydride, NaBH₄. This is a water-soluble salt containing the tetrahedral BH₄⁻ anion, which is isoelectronic with methane but has a negative charge since boron has one less proton in the nucleus than does carbon.

But beware! The boron’s negative charge doesn’t mean that there is a lone pair on boron—there isn’t. You cannot draw an arrow coming out of this charge to form another bond. If you did, you would get a pentacovalent B(V) compound, which would have 10 electrons in its outer shell. Such a thing is impossible with a first row element as there are only four available orbitals (1 $\times$ 2s and 3 $\times$ 2p). Instead, since all of the electrons (including that represented by the negative charge) are in B–H $\sigma$ orbitals, it is from a B–H bond that we must start any arrow to indicate reaction of BH₄⁻ as a nucleophile. By transferring this pair of electrons we make the boron atom neutral—it is now trivalent with just six electrons.

What happens when we carry out this reaction using a carbonyl compound as the electrophile? The hydrogen atom, together with the pair of electrons from the B–H bond, will be transferred to the carbon atom of the C=O group.

Though no hydride ion, H–, is actually involved in the reaction, the transfer of a hydrogen atom with an attached pair of electrons can be regarded as a ‘hydride transfer’. You will often see it described this way in books. But be careful not to confuse BH₄⁻ with the hydride ion itself. To make it quite clear that it is the hydrogen atom that is forming the new bond to C, this reaction may also be helpfully represented with a curly arrow passing through the hydrogen atom.

The oxyanion produced in the first step can help stabilize the electron-deficient BH₃ molecule by adding to its empty p orbital. Now we have a tetravalent boron anion again, which could transfer a second hydrogen atom (with its pair of electrons) to another molecule of aldehyde.
This process can continue so that, in principle, all four hydrogen atoms could be transferred to molecules of aldehyde. In practice the reaction is rarely as efficient as that, but aldehydes and ketones are usually reduced in good yield to the corresponding alcohol by sodium borohydride in water or alcoholic solution. The water or alcohol solvent provides the proton needed to form the alcohol from the alkoxide.

Sodium borohydride is one of the weakest hydride donors available. The fact that it can be used in water is evidence of this as more powerful hydride donors such as lithium aluminium hydride, LiAlH₄, react violently with water. Sodium borohydride reacts with both aldehydes and ketones, though the reaction with ketones is slower: for example, benzaldehyde is reduced about 400 times faster than acetophenone in isopropanol.

Sodium borohydride does not react at all with less reactive carbonyl compounds such as esters or amides: if a molecule contains both an aldehyde and an ester, only the aldehyde will be reduced.

The next two examples illustrate the reduction of aldehydes and ketones in the presence of other reactive functional groups. No reaction occurs at the nitro group in the first case or at the alkyl halide in the second.
Addition of organometallic reagents to aldehydes and ketones

The next type of nucleophile we shall consider is the organometallic reagent. Lithium and magnesium are very electropositive metals, and the Li–C or Mg–C bonds in organolithium or organomagnesium reagents are highly polarized towards carbon. They are therefore very powerful nucleophiles, and attack the carbonyl group to give alcohols, forming a new C–C bond. For our first example, we shall take one of the simplest of organolithiums, methyllithium, which is commercially available as a solution in Et₂O, shown here reacting with an aldehyde. The orbital diagram of the addition step shows how the polarization of the C–Li bond means that it is the carbon atom of the nucleophile that attacks the carbon atom of the electrophile and we get a new C–C bond.

The course of the reaction is much the same as you have seen before, but we need to highlight a few points where this reaction scheme differs from those you have met earlier in the chapter. First of all, notice the legend ‘1. MeLi, THF; 2. H₂O’. This means that, first, MeLi is added to the aldehyde in a THF solvent. Reaction occurs: MeLi adds to the aldehyde to give an alkoxide. Then (and only then) water is added to protonate the alkoxide. The ‘2. H₂O’ means that water is added in a separate step only when all the MeLi has reacted: it is not present at the start of the reaction as it was in the cyanide reaction and some of the borohydride addition reactions. In fact, water must not be present during the addition of MeLi (or of any other organometallic reagent) to a carbonyl group because water destroys organometallics very rapidly by protonating them to give alkanes (organolithiums and organomagnesiums are strong bases as well as powerful nucleophiles). The addition of water, or sometimes dilute acid or ammonium chloride, at the end of the reaction is known as the work-up.

Because they are so reactive, organolithiums are usually reacted at low temperature, often –78 °C (the sublimation temperature of solid CO₂), in aprotic solvents such as Et₂O or THF. Organolithiums also react with oxygen, so they have to be handled under a dry, inert atmosphere of nitrogen or argon.

Other common, and commercially available, organolithium reagents include n-butyllithium and phenyllithium, and they react with both aldehydes and ketones. Note that addition to an aldehyde gives a secondary alcohol while addition to a ketone gives a tertiary alcohol.

Organomagnesium reagents known as Grignard reagents (RMgX) react in a similar way. Some simple Grignard reagents, such as methyl magnesium chloride, MeMgCl, and phenyl magnesium bromide, PhMgBr, are commercially available, and the scheme shows PhMgBr reacting with an aldehyde. The reactions of these two classes of organometallic reagent—organolithiums and Grignard reagents—with carbonyl compounds are among the most important ways of making carbon–carbon bonds, and we will consider them in more detail in Chapter 9.
Addition of water to aldehydes and ketones

Nucleophiles don’t have to be highly polarized or negatively charged to react with aldehydes and ketones: neutral ones will as well. How do we know? This $^{13}$C NMR spectrum was obtained by dissolving formaldehyde, $\text{H}_2\text{C}=\text{O}$, in water. You will remember from Chapter 3 that the carbon atoms of carbonyl groups give $^{13}$C signals typically in the region of 150–200 p.p.m. So where is formaldehyde’s carbonyl peak? Instead we have a signal at 83 p.p.m.—where we would expect tetrahedral carbon atoms singly bonded to oxygen to appear.

What has happened is that water has added to the carbonyl group to give a compound known as a hydrate or 1,1-diol.

This reaction, like the cyanohydrin formation we discussed at the beginning of the chapter, is an equilibrium, and is quite general for aldehydes and ketones. But, as with the cyanohydrins, the position of the equilibrium depends on the structure of the carbonyl compound. Generally, the same steric factors (pp. 138–139) mean that simple aldehydes are hydrated to some extent while simple ketones are not. However special factors can shift the equilibrium towards the hydrated form even for ketones, particularly if the carbonyl compound is reactive or unstable.

Formaldehyde is an extremely reactive aldehyde as it has no substituents to hinder attack—it is so reactive that it is rather prone to polymerization (Chapter 52). And it is quite happy to move from sp$^2$ to sp$^3$ hybridization because there is very little increased steric hindrance between the two hydrogen atoms as the bond angle changes from 120° to 109° (p. 139). This is why our aqueous solution of formaldehyde contains essentially no $\text{CH}_2\text{O}$—it is completely hydrated. A mechanism for the hydration reaction is shown below. Notice how a proton has to be transferred from one oxygen atom to the other, mediated by water molecules.
Formaldehyde reacts with water so readily because its substituents are very small: a steric effect. Electronic effects can also favour reaction with nucleophiles—electronegative atoms such as halogens attached to the carbon atoms next to the carbonyl group can increase the extent of hydration according to the number of halogen substituents and their electron-withdrawing power. They increase the polarization of the carbonyl group, which already has a positively polarized carbonyl carbon, and make it even more prone to attack by water. Trichloroacetaldehyde (chloral, Cl₃CHO) is hydrated completely in water, and the product ‘chloral hydrate’ can be isolated as crystals and is an anaesthetic. You can see this quite clearly in the two IR spectra. The first one is a spectrum of chloral hydrate from a bottle—notice there is no strong absorption between 1700 and 1800 cm⁻¹ (where we would expect C=O to appear) and instead we have the tell-tale broad O–H peak at 3400 cm⁻¹. Heating drives off the water, and the second IR spectrum is of the resulting dry chloral: the C=O peak has reappeared at 1770 cm⁻¹, and the O–H peak has gone.

The chart shows the extent of hydration (in water) of a small selection of carbonyl compounds: hexafluoroacetone is probably the most hydrated carbonyl compound possible!

Cyclopropanones—three-membered ring ketones—are also hydrated to a significant extent, but for a different reason. You saw earlier how acyclic ketones suffer increased steric hindrance when the bond angle changes from 120° to 109° on moving from sp² to sp³ hybridization. Cyclopropanones...
(and other small-ring ketones) conversely prefer the small bond angle because their substituents are already confined within a ring. Look at it this way: a three-membered ring is really very strained, with bond angles forced to be 60°. For the sp² hybridized ketone this means bending the bonds 60° away from their ‘natural’ 120°. But for the sp³ hybridized hydrate the bonds have to be distorted by only 49° (= 109° – 60°). So addition to the C=O group allows some of the strain inherent in the small ring to be released—hydration is favoured, and indeed cyclopropanone and cyclobutanone are very reactive electrophiles.

The same structural features that favour or disfavour hydrate formation are important in determining the reactivity of carbonyl compounds with other nucleophiles, whether the reactions are reversible or not. Steric hindrance and more alkyl substituents make carbonyl compounds less reactive towards any nucleophile; electron-withdrawing groups and small rings make them more reactive.

**Hemiacetals from reaction of alcohols with aldehydes and ketones**

Since water adds to (at least some) carbonyl compounds, it should come as no surprise that alcohols do too. The product of the reaction is known as a hemiacetal, because it is halfway to an acetal, a functional group, which you met in Chapter 2 (p. 35) and which will be discussed in detail in Chapter 14. The mechanism follows in the footsteps of hydrate formation: just use ROH instead of HOH.

A proton has to be transferred from one oxygen atom to the other: we have shown ethanol doing this job, with one molecule being protonated and one deprotonated. There is no overall consumption of ethanol in the protonation/deprotonation steps, and the order in which these steps happen is not important. In fact, you could reasonably write them in one step as shown in the margin, without involving the alcohol, and we do this in the next hemiacetal-forming reaction below. As with all these carbonyl group reactions, what is really important is the addition step, not what happens to the protons.

Hemiacetals formation is reversible, and hemiacetals are stabilized by the same special structural features as those of hydrates. However, hemiacetals can also gain stability by being cyclic—when the carbonyl group and the attacking hydroxyl group are part of the same molecule. The reaction is now an intramolecular (within the same molecule) addition, as opposed to the intermolecular (between two molecules) ones we have considered so far.

*Intermolecular reactions occur between two molecules*

*Intramolecular reactions occur within the same molecule*

We shall discuss the reasons why intramolecular reactions are more favourable, and why cyclic hemiacetals and acetals are more stable, in Chapter 14.
Although the cyclic hemiacetal (also called ‘lactol’) product is more stable, it is still in equilibrium with some of the open-chain hydroxyaldehyde form. Its stability, and how easily it forms, depend on the size of the ring: five- and six-membered rings are free from strain (their bonds are free to adopt 109° or 120° angles—compare the three-membered rings on p. 145), and five- or six-membered hemiacetals are common. Among the most important examples are many sugars. Glucose, for example, is a hydroxyaldehyde that exists mainly as a six-membered cyclic hemiacetal (>99% of glucose is cyclic in solution), while ribose exists as a five-membered cyclic hemiacetal.

### Ketones can form hemiacetals

Hydroxyketones also form hemiacetals, but (as you should now expect) they usually do so less readily than hydroxyaldehydes. However, this hydroxyketone must exist solely as the cyclic hemiacetal because it shows no C=O stretch in its IR spectrum. The reason? The starting hydroxyketone is already cyclic, with the hydroxyl group poised to attack the ketone— it can’t get away, so cyclization is highly favoured.

### Acid and base catalysis of hemiacetal and hydrate formation

In Chapter 8 we shall look in detail at acids and bases, but at this point we need to tell you about one of their important roles in chemistry: they act as catalysts for a number of carbonyl addition reactions, among them hemiacetal and hydrate formation. To see why, we need to look back at the mechanisms of hemiacetal formation on p. 145 and hydrate formation on p. 143. Both involve proton-transfer steps like this.

A catalyst increases the rate of a chemical reaction but emerges from the reaction unchanged.

In the first proton-transfer step, ethanol acts as a base, removing a proton; in the second it acts as an acid, donating a proton. Strong acids or strong bases (for example, HCl or NaOH) increase the rate of hemiacetal or hydrate formation because they allow these proton-transfer steps to occur before the addition to the carbonyl group.
In acid (dilute HCl, say), this is the mechanism. The first step is now protonation of the carbonyl group’s lone pair: the positive charge makes it much more electrophilic so the addition reaction is faster. Notice how the proton added at the beginning is lost again at the end—it really is a catalyst. In acid it is also possible for the hemiacetal to react further with the alcohol to form an acetal, but this need not concern you at present.

And this is the mechanism in basic solution. The first step is now deprotonation of the ethanol by hydroxide, which makes the addition reaction faster by making the ethanol more nucleophilic. Again, base (hydroxide) is regenerated in last step, making the overall reaction catalytic in base. The reaction in base always stops with the hemiacetal—acetals never form in base.

The final step could equally well involve deprotonation of ethanol to give alkoxide—and alkoxide could equally well do the job of catalysing the reaction. In fact, you will often come across mechanisms with the base represented just as ‘B–’ because it doesn’t matter what the base is.

These two mechanisms typify acid- and base-catalysed additions to carbonyl groups and we can summarize the effects of the two catalysts.

- For nucleophilic additions to carbonyl groups:
  - Acid catalysts work by making the carbonyl group more electrophilic
  - Base catalysts work by making the nucleophile more nucleophilic

Acid and base catalysis of hemiacetal and hydrate formation
Bisulfite addition compounds

The last nucleophile of this chapter, sodium bisulfite, NaHSO₃, adds to aldehydes and some ketones to give what is usually known as a **bisulfite addition compound**. The reaction occurs by nucleophilic attack of a lone pair on the carbonyl group, just like the attack of cyanide. This leaves a positively charged sulfur atom but a simple proton transfer leads to the product.

The products are useful for two reasons. They are usually crystalline and so can be used to purify liquid aldehydes by recrystallization. This is of value only because this reaction, like several you have met in this chapter, is reversible. The bisulfite compounds are made by mixing the aldehyde or ketone with saturated aqueous sodium bisulfite in an ice bath, shaking, and crystallizing. After purification the bisulfite addition compound can be hydrolysed back to the aldehyde in dilute aqueous acid or base.

The reversibility of the reaction makes bisulfite compounds useful intermediates in the synthesis of other adducts from aldehydes and ketones. For example, one practical method for making cyanohydrins involves bisulfite compounds. The famous practical book 'Vogel' suggests reacting acetone first with sodium bisulfite and then with sodium cyanide to give a good yield (70%) of the cyanohydrin.

What is happening here? The bisulfite compound forms first, but only as an intermediate on the route to the cyanohydrin. When the cyanide is added, reversing the formation of the bisulfite compound provides the single proton necessary to give back the hydroxyl group at the end of the reaction. No dangerous HCN is released (always a hazard when cyanide ions and acid are present together).
The bisulfite compound of formaldehyde (CH₂O) has special significance. Earlier in this chapter we mentioned the difficulty of working with formaldehyde because it is either an aqueous solution or a dry polymer. One readily available monomeric form is the bisulfite compound. It can be made in water (in which it is soluble) but addition of ethanol (in which it isn’t) causes it to crystallize out.

The compound is commercially available and, together with the related zinc salt, is widely used in the textile industry as a reducing agent.

The second reason that bisulfite compounds are useful is that they are soluble in water. Some small (that is, low molecular weight) aldehydes and ketones are water-soluble—acetone is an example. But most larger (more than four or so carbon atoms) aldehydes and ketones are not. This does not usually matter to most chemists as we often want to carry out reactions in organic solvents rather than water. But it can matter to medicinal chemists, who make compounds that need to be compatible with biological systems. And in one case, the solubility of bisulfite adduct in water is literally vital.

Dapsone is an antileprosy drug. It is a very effective one too, especially when used in combination with two other drugs in a ‘cocktail’ that can be simply drunk as an aqueous solution by patients in tropical countries without any special facilities, even in the open air. But there is a problem! Dapsone is insoluble in water.

The solution is to make a bisulfite compound from it. You may ask how this is possible since dapsone has no aldehyde or ketone—just two amino groups and a sulfone. The trick is to use the formaldehyde bisulfite compound and exchange the OH group for one of the amino groups in dapsone.

Now the compound will dissolve in water and release dapsone inside the patient. The details of this sort of chemistry will come in Chapter 14 when you will meet imines as intermediates. But at this stage we just want you to appreciate that even the relatively simple chemistry in this chapter is useful in synthesis, in commerce, and in medicine.
Problems

1. Draw mechanisms for these reactions.

\[
\begin{align*}
\text{O} & \xrightarrow{\text{NaBH}_4} \text{OH} \\
\text{CHO} & \xrightarrow{\text{LiAlH}_4} \text{OH}
\end{align*}
\]

2. Cyclopropanone exists as the hydrate in water but 2-hydroxyethanal does not exist as its hemiacetal. Explain.

\[
\begin{align*}
\text{cyclopropanone} & \rightarrow \text{hydrate} \\
\text{2-hydroxyethanal} & \xrightarrow{\text{hemiacetal}} \text{hemiacetal}
\end{align*}
\]

3. One way to make cyanohydrins is illustrated here. Suggest a detailed mechanism for the process.

\[
\begin{align*}
\text{R} & \xrightarrow{\text{Me}_3\text{SiCN}} \text{R} \xrightarrow{\text{cat KCN}} \text{R} \xrightarrow{\text{NaBH}_4} \text{Cl}_3\text{C} \xrightarrow{\text{H}_2\text{O}} \text{Cl}_3\text{C} \xrightarrow{\text{H}_2\text{O}} \text{H}_2\text{O}, \text{HCl}
\end{align*}
\]

4. There are three possible products from the reduction of this compound with sodium borohydride. What are their structures? How would you distinguish them spectroscopically, assuming you can isolate pure compounds?

5. The triketone shown here is called ‘ninhydrin’ and is used for the detection of amino acids. It exists in aqueous solution as a monohydrate. Which of the three ketones is hydrated and why?

\[
\begin{align*}
\text{ninhydrin}
\end{align*}
\]

6. This hydroxyketone shows no peaks in its infrared spectrum between 1600 and 1800 cm\(^{-1}\) but it does show a broad absorption at 3000 to 3400 cm\(^{-1}\). In the \(^{13}\text{C}\) NMR spectrum, there are no peaks above 150 p.p.m. but there is a peak at 110 p.p.m. Suggest an explanation.

7. Each of these compounds is a hemiacetal and therefore formed from an alcohol and a carbonyl compound. In each case give the structure of these original materials.

\[
\begin{align*}
\text{hemiacetal}
\end{align*}
\]

8. Trichloroethanol may be prepared by the direct reduction of chloral hydrate in water with sodium borohydride. Suggest a mechanism for this reaction. (Warning! Sodium borohydride does not displace hydroxide from carbon atoms!)

\[
\begin{align*}
\text{chloral hydrate} & \xrightarrow{\text{NaBH}_4} \text{trichloroethanol}
\end{align*}
\]

9. It has not been possible to prepare the adducts from simple aldehydes and HCl. What would be the structure of such compounds, if they could be made, and what would be the mechanism of their formation? Why cannot these compounds in fact be made?

10. What would be the products of these reactions? In each case give a mechanism to justify your predictions.

\[
\begin{align*}
\text{CHO} & \xrightarrow{\text{NaCN}} ? \\
\text{CHO} & \xrightarrow{\text{EtMgBr}} ? \\
\text{NaBH}_4 & \xrightarrow{?}
\end{align*}
\]

11. The equilibrium constant \(K_{eq}\) for formation of the cyanohydrin of cyclopentanone and HCN is 67, while for butan-2-one and HCN it is 28. Explain.
Introduction

As you look around you, you will be aware of many different colours—from the greens and browns outside to the bright blues and reds of the clothes you are wearing. All these colours result from the interaction of light with the pigments in these different things—some frequencies of light are absorbed, others scattered. Inside our eyes, chemical reactions detect these different frequencies and convert them into electrical nerve impulses sent to the brain. All these different pigments have one thing in common—lots of double bonds. For example, the pigment responsible for the red colour in tomatoes, lycopene, is a long-chain polyalkene.

Lycopene contains only carbon and hydrogen while most pigments contain many other elements but nearly all contain double bonds. This chapter is about the properties, such as colour, of molecules that have several double bonds and that depend on the joining up or conjugation of the electrons in these double bonds.

In earlier chapters, we talked about basic carbon skeletons made up of \( \sigma \) bonds. In this chapter we shall see how, in some cases, we can also have a large \( \pi \) framework spread over many atoms and how this dominates the chemistry of such compounds. We shall see how this \( \pi \) framework is responsible for the otherwise unexpected stability of certain cyclic polyunsaturated compounds, including benzene and other aromatic compounds. We shall also see how this framework gives rise to the many colours in our world. To understand such molecules properly, we need to start with the simplest of all unsaturated compounds, ethene.

The structure of ethene (ethylene, \( \text{CH}_2=\text{CH}_2 \))

The structure of ethene (ethylene) is well known. It has been determined by electron diffraction and is planar (all atoms are in the same plane) with the bond lengths and angles shown below. The carbon atoms are roughly trigonal and the C–C bond distance is shorter than that of a C–C \( \sigma \) bond.
We shall use the approach of Chapter 4 (p. 106) and rationalize the shapes of molecular orbitals by combining the atomic orbitals of the atoms involved using the LCAO (Linear Combination of Atomic Orbitals) approach. Hybridizing the atomic orbitals first makes this simpler. We mix the 2s orbital on each carbon atom with two of the three 2p orbitals to give three sp\(^2\) orbitals leaving the third p orbital unchanged. Two of the sp\(^2\) orbitals overlap with the hydrogen 1s orbitals to form molecular orbitals, which will be the C–H σ bonds. The other sp\(^2\) orbital forms the σ C–C bond by overlapping with the sp\(^2\) orbital on the other carbon. The remaining p orbital can overlap with the p orbital on the other carbon to form a molecular orbital that represents the \(\pi\) bond.

Ethene is chemically more interesting than ethane because of the \(\pi\) bond. In fact, the \(\pi\) bond is the most important feature of ethene. In the words of Chapter 5, the C–C \(\pi\) orbital is the HOMO (Highest Occupied Molecular Orbital) of the alkene, which means that the electrons in it are more available than any others to react with something that wants electrons (an electrophile). Since this orbital is so important, we will look at it more closely.

The \(\pi\) orbital results from combining the two 2p orbitals of the separate carbon atoms. Remember that when we combine two atomic orbitals we get two molecular orbitals. These result from combining the p orbitals either in-phase or out-of-phase. The in-phase combination accounts for the bonding molecular orbital (\(\pi\)), whilst the out-of-phase combination accounts for the anti-bonding molecular orbital (\(\pi^*\)). As we progress to compounds with more than one alkene, so the number of \(\pi\) orbitals will increase but will remain the same as the number of \(\pi^*\) orbitals.

The \(\pi\) bond contains two electrons and, since we fill up the energy level diagram from the lowest-energy orbital upwards, both these electrons go into the bonding molecular orbital. In order to have a strong \(\pi\) bond, the two atomic p orbitals must be able to overlap effectively. This means they must be parallel.
There are two isomers (cis and trans or E and Z) of many alkenes

The π bond has electron density both above and below the σ bond as the parallel p orbitals overlap locking the bond rigid. Hence no rotation is possible about a double bond—the π bond must be broken before rotation can occur. One consequence of this locking effect of the double bond is that there are two isomers of a disubstituted alkene. One is called a cis or Z alkene, the other a trans or E alkene.

Alkenes resist rotation

Maleic and fumaric acids were known in the nineteenth century to have the same chemical composition and the same functional groups and yet they were different compounds—why remained a mystery. That is, until 1874 when van’t Hoff proposed that free rotation about double bonds was restricted. This meant that, whenever each carbon atom of a double bond had two different substituents, isomers would be possible. He proposed the terms cis (Latin meaning ‘on this side’) and trans (Latin meaning ‘across or on the other side’) for the two isomers. The problem was: which isomer was which? On heating, maleic acid readily loses water to become maleic anhydride so this isomer must have both acid groups on the same side of the double bond.

It is possible to interconvert cis and trans alkenes, but the π bond must be broken first. This requires a considerable amount of energy—around 260 kJ mol$^{-1}$. One way to break the π bond would be to promote an electron from the π orbital to the π$^*$ orbital (from HOMO to LUMO). If this were to happen, there would be one electron in the bonding π orbital and one in the antibonding π$^*$ orbital and hence no overall bonding. Electromagnetic radiation of the correct energy could promote the electron from HOMO to LUMO. The correct energy actually corresponds to light in the ultraviolet (UV) region of the spectrum. Thus, shining UV light on an alkene would promote an electron from its bonding π molecular orbital to its antibonding π$^*$ molecular orbital, thereby breaking the π bond (but not the σ bond) and allowing rotation to occur.

Molecules with more than one C–C double bond

Benzene has three strongly interacting double bonds

The rest of this chapter concerns molecules with more than one C–C double bond and what happens to the π orbitals when they interact. To start, we shall take a bit of a jump and look at the structure of benzene. Benzene has been the subject of considerable controversy since its discovery in 1825. It was
soon worked out that the formula was C₆H₆, but how were these atoms arranged? Some strange structures were suggested until Kekulé proposed the correct structure in 1865.

Let’s look at the molecular orbitals for Kekulé’s structure. As in simple alkenes, each of the carbon atoms is sp² hybridized leaving the remaining p orbital free.

The σ framework of the benzene ring is like the framework of an alkene. The problem comes with the p orbitals—which pairs do we combine to form the π bonds? There seem to be two possibilities.

With benzene itself, these two forms are equivalent but, if we had a 1,2- or a 1,3-disubstituted benzene compound, these two forms would be different. A synthesis was designed for these two compounds but it was found that both compounds were identical. This posed a bit of a problem to Kekulé—his structure didn’t seem to work after all. His solution was that benzene rapidly equilibrates, or ‘resonates’ between the two forms to give an averaged structure in between the two.

The molecular orbital answer to this problem, as you may well know, is that all six p orbitals can combine to form (six) new molecular orbitals, one of which (the one lowest in energy) consists of a ring of electron density above and below the plane of the molecule. Benzene does not resonate between the two Kekulé structures—the electrons are in molecular orbitals spread equally over all the carbon atoms. However the term ‘resonance’ is still sometimes used (but not in this book) to describe this mixing of molecular orbitals.

We shall describe the π electrons in benzene as delocalized, that is, no longer localized in specific double bonds between two particular carbon atoms but spread out, or delocalized, over all six atoms in the ring. An alternative drawing for benzene shows the π system as a ring and does not put in the double bonds.
We are saying that the π electrons are not localized in alternating double bonds but are actually spread out over the whole system in a molecular orbital shaped like a ring (we will look at the shapes of the others later). The electrons are therefore said to be delocalized. Theoretical calculations confirm this model, as do experimental observations. Electron diffraction studies show benzene to be a regular, planar hexagon with all the carbon–carbon bond lengths identical (139.5 pm). This bond length is in between that of a carbon–carbon single bond (154.1 pm) and a full carbon–carbon double bond (133.7 pm). A further strong piece of evidence for this ring of electrons is revealed by proton NMR and is discussed on p. 251.

Noncyclic polyenes

What would the structure be like if the three C–C double bonds were not in a ring as they are in benzene but were instead in a chain. What is the structure of hexatriene? Are the bond lengths still all the same?

There are two isomers of hexatriene: a cis form and a trans form. The name refers to the geometry about the central double bond. The two isomers have different chemical and physical properties. Rotation is still possible about the single bonds (although slightly more difficult than around a normal single bond) and there are three different planar conformations possible for each isomer. Keeping the central black double bond the same, we can rotate about each of the green σ bonds in turn. Each row simply shows different ways to draw the same compound.

---

**Delocalization terminology**

What words should be used to describe delocalization is a vexed question. Terms such as resonance, mesomerism, conjugation, and delocalization are only a few of the ones you will find in books. You will already have noticed that we don’t like ‘resonance’ because it suggests that the structure vibrates rapidly between localized structures. We shall use conjugation and delocalization: conjugation focuses on the sequence of alternating double and single bonds while delocalization focuses on the molecular orbitals covering the whole system. Electrons are delocalized over the whole of a conjugated system.
The structures of both cis- and trans-hexatriene have been determined by electron diffraction and two important features emerge.

- Both structures are essentially planar (the cis form is not quite for steric reasons)
- There are double and single bonds but the central double bond in each case is slightly longer than the end double bonds and the single bonds are slightly shorter than a ‘standard’ single bond

The most stable structure of trans-hexatriene is shown here.

Why is this structure planar and why are the bond lengths different from their ‘standard’ values? This sounds like the situation with benzene and again the answers lie in the molecular orbitals that can arise from the combination of the six p orbitals. Just as in benzene, these orbitals can all combine to give one big molecular orbital over the whole molecule. However, the p orbitals can overlap and combine only if the molecule is planar.

Since the p orbitals on carbons 2 and 3 overlap, there is some partial double bond character in the central σ bond, helping to keep the structure planar. This overlap means that it is slightly harder to rotate this ‘formal single bond’ than might be expected—it requires about 30 kJ mol$^{-1}$ to rotate it whereas the barrier in propene is only around 3 kJ mol$^{-1}$.

This explains why the compound adopts a planar structure but, in order to understand why the bond lengths are slightly different from their expected values or even why they are not all the same as in benzene, we must look at the all the molecular orbitals for hexatriene. Before we can do this, we must first study some simpler systems and address the important question of conjugation seriously.

Conjugation

In benzene and hexatriene every carbon atom is sp$^2$ hybridized with the remaining p orbital available to overlap with its neighbours. The uninterrupted chain of p orbitals is a consequence of having alternate double and single bonds. When two double bonds are separated by just one single bond, the two double bonds are said to be conjugated. Conjugated double bonds have different properties from isolated double bonds, both physically (they are often longer as we have already seen) and chemically (Chapters 10, 23, and 35).

Conjugated systems

In the dictionary, ‘conjugated’ is defined, among other ways, as ‘joined together, especially in pairs’ and ‘acting or operating as if joined’. This does indeed fit very well with the behaviour of such conjugated double bonds since the properties of a conjugated system are often different from those of the component parts. We are using conjugation to describe bonds and delocalization to describe electrons.
You have already met several conjugated systems: remember lycopene at the start of this chapter and β-carotene in Chapter 3? All eleven double bonds in β-carotene are separated by only one single bond. We again have a long chain in which all the p orbitals can overlap to form molecular orbitals.

It is not necessary to have two carbon–carbon double bonds in order to have a conjugated system—the C–C and C–O double bonds of propenal (acrolein) are also conjugated. The chemistry of such conjugated carbonyl compounds is significantly different from the chemistry of their component parts (Chapter 10).

What is important though is that the double bonds are separated by one and only one single bond. Remember the unsaturated fatty acid, linoleic acid, that you met in Chapter 3? Another fatty acid with even more unsaturation is arachidonic acid. None of the four double bonds in this structure are conjugated since in between any two double bonds there is an sp³ carbon. This means there is no p orbital available to overlap with the ones from the double bonds. The saturated carbon atoms insulate the double bonds from each other.

If an atom has two double bonds directly attached to it, that is, there are no single bonds separating them, again no conjugation is possible. The simplest compound with such an arrangement is allene. If we look at the arrangement of the p orbitals in this system, it is easy to see why no delocalization is possible—the two π bonds are perpendicular to each other.

**Requirements for conjugation**

- Conjugation requires double bonds separated by one single bond
- Separation by two single bonds or no single bonds will not do
The allyl system

The allyl cation

We would not say that two p orbitals are conjugated—they just make up a double bond—so just how many p orbitals do we need before something can be described as conjugated? It should be clear that in butadiene the double bonds are conjugated—here we have four p orbitals.

Is it possible to have three p orbitals interacting? How can we get an isolated p orbital—after all, we can't have half a double bond. Let us look for a moment at allyl bromide (prop-2-enyl bromide or 1-bromoprop-2-ene). Carbon 1 in this compound has got four atoms attached to it (a carbon, two hydrogens, and a bromine atom) so it is tetrahedral (or sp3 hybridized).

Bromine is more electronegative than carbon and so the C–Br bond is polarized towards the bromine. If this bond were to break completely, the bromine would keep both electrons from the C–Br bond to become bromide ion, Br–, leaving behind an organic cation. The end carbon would now only have three groups attached and so it becomes trigonal (sp2 hybridized). This leaves a vacant p orbital that we can combine with the \( \pi \) bond to give a new molecular orbital for the allyl system.

Rather than trying to combine the p orbital with the \( \pi \) bond, it is easier for us to consider how three p orbitals combine; after all, we thought of the \( \pi \) bond as a combination of two p orbitals. Since we are combining three atomic orbitals (the three 2p orbitals on carbon) we shall get three molecular orbitals. The lowest-energy orbital will have them all combining in-phase. This is a bonding orbital since all the interactions are bonding.

The next orbital requires one orbital, just as higher-energy atomic orbitals have extra nodes (Chapter 4). The only way to include a node and maintain the symmetry of the system is to put the node through the central atom. This means that when this orbital is occupied there will be no electron density on this central atom. Since there are no interactions between adjacent atomic orbitals (either bonding or antibonding), this is a nonbonding orbital.

The final molecular orbital must have two nodal planes. All the interactions of the atomic orbitals are out-of-phase so the resulting molecular orbital is an antibonding orbital.
We can summarize all this information in a molecular orbital energy level diagram.

The two electrons that were in the \( \pi \) bond now occupy the orbital lowest in energy, the bonding molecular orbital \( \Psi_1 \), and now spread over three carbon atoms. The electrons highest in energy and so most reactive are those in the HOMO. However, in this case, since the allyl cation has an overall positive charge, we wouldn’t really expect it to act as a nucleophile. Of far more importance is the vacant nonbonding molecular orbital—the LUMO, the nonbonding \( \Psi_2 \). It is this orbital that must be attacked if the allyl cation reacts with a nucleophile. From the shape of the orbital, we can see that the incoming electrons will attack the end carbon atoms not the middle one since, if this orbital were full, all electron density in it would be on the end carbon atoms, not the middle one. A different way of looking at this is to see which carbon atoms in the system are most lacking in electron density. The only orbital in this case with any electrons in it is the bonding molecular orbital \( \Psi_1 \). From the relative sizes of the coefficients on each atom we can see that the middle carbon has more electron density on it than the end ones; therefore the end carbons must be more positive than the middle one and so a nucleophile would attack the end carbons.

Representations of the allyl cation

How can we represent all this information with curly arrows? The simple answer is that we can’t. Curly arrows show the movement of a pair of electrons. The electrons are not really moving around in this system—they are simply spread over all three carbon atoms with most electron density on the middle carbon. Curly arrows can give us an indication of the equivalence of the two end carbons, showing that the positive charge is shared over these two atoms.

The curly arrows we used in this representation are slightly different from the curly arrows we used (Chapter 5) to represent mechanisms by the forming and breaking of bonds. We still arrive at the second structure by supposing that the curly arrows mean the movement of two electrons so that the right-hand structure results from the ‘reaction’ shown on the left-hand structure, but these ‘reactions’ would be the movement of electrons and nothing more. In particular, no atoms have moved and no \( \sigma \) bonds have been formed or broken. These two structures are just two different ways of
drawing the same species. The arrows are delocalization arrows and we use them to remind us that our simple fixed-bond structures do not tell the whole truth. To remind us that these are delocalization arrows, we use a different reaction arrow, a single line with arrowheads on each end (↔).

The problem with these structures is that they seem to imply that the positive charge (and the double bond for that matter) is jumping from one end of the molecule to the other. This, as we have seen, is just not so. Another and perhaps better picture uses dotted lines and partial charges. However, as in the representation of benzene with a circle in the middle, we cannot draw mechanisms on this structure. Each of the representations has its value and we shall use both.

A summary of the allyl cation system

- The two electrons in the π system are spread out over all three carbon atoms with most electron density on the central carbon
- There are no localized double and single bonds—both C–C bonds are identical and in between a double and single bond
- Both end carbons are equivalent
- The positive charge is shared equally over the two end carbons. The LUMO of the molecule shows us that this is the site for attack by a nucleophile

The delocalized allyl cation can be compared to localized carbocations by NMR

In the reaction below, a very strong acid (called ‘supercid’—see Chapter 17) protonates the OH group of 3-cyclohexenol, which can then leave as water. The resulting cation is, not surprisingly, unstable and would normally react rapidly with a nucleophile. However, at low temperatures and if there are no nucleophiles present, the cation is relatively stable and it is even possible to record a carbon NMR spectrum (at –80 °C).

The NMR spectrum of this allylic cation reveals a plane of symmetry, which confirms that the positive charge is spread over two carbons. The large shift of 224 p.p.m. for these carbons indicates very strong deshielding (that is, lack of electrons) but is nowhere near as large as a localized cation. The middle carbon’s shift of 142 p.p.m. is almost typical of a normal double bond indicating that it is neither significantly more nor less electron-rich than normal.

**Carbocation ¹³C shift**

This localized carbocation shows an enormous shift of 330 p.p.m. indicating very little shielding of the positively charged carbon atom. Again, due to the instability of this species, the ¹³C spectrum was recorded at low temperature.

This carbon resonates at 330 p.p.m.
The allyl radical

When we made the allyl cation from allyl bromide, the bromine atom left as bromide ion taking both the electrons from the C–Br bond with it—the C–Br bond broke heterolytically. What if the bond broke homolytically—that is, carbon and bromine each had one electron? A bromine atom and an allyl radical (remember a radical has an unpaired electron) would be formed. This reaction can be shown using the single-headed fish hook curly arrows from Chapter 5: normal double-headed arrows show the movement of two electrons; single-headed arrows show the movement of one.

Now the end carbon has a single unpaired electron. What do we do with it? Before the bond broke, the end carbon was tetrahedral (sp³ hybridized). We might think that the single electron would still be in an sp³ orbital. However, since an sp³ orbital cannot overlap efficiently with a π bond, the single electron would then have to be localized on the end carbon atom. If the end carbon atom becomes trigonal (sp² hybridized), the single electron could be in a p orbital and this could overlap and combine with the π bond. This would mean that the radical could be spread over the molecule in the same orbital that contained the cation.

So once again we have three p orbitals to combine. This is the same situation as before. We have the same atoms, the same orbitals, and so the same energy levels. In fact, the molecular orbital energy level diagram for this compound is almost the same as the one for the allyl cation: the only difference is the number of electrons in the π system. Whereas in the allyl cation π system we only had two electrons, here we have three (two from the π bond plus the single one). Where does this extra electron go? Answer: in the next lowest molecular orbital—the nonbonding molecular orbital.

The allyl anion

What would have happened if both electrons from the C–Br bond in allyl bromide had stayed behind on the carbon? If we had removed the bromine atom with a metal, magnesium for example (Chapter 9), both electrons would remain leaving an overall negative charge on the allyl system.
Again, this system is much more stable if the negative charge can be spread out rather than localized on one end carbon. This can be accomplished only if the negative charge is in a p orbital rather than an sp³ orbital. The molecular orbital energy level diagram is, of course, unchanged: all we have to do is put the extra electron in the nonbonding orbital. Altogether we now have four electrons in the π system—two from the π bond and two from the negative charge. Both the bonding and the nonbonding orbitals are now fully occupied.

Where is the electron density in the allyl anion π system? The answer is slightly more complicated than that for the allyl cation because now we have two full molecular orbitals and the electron density comes from a sum of both orbitals. This means there is electron density on all three carbon atoms. However, the HOMO for the anion is now the nonbonding molecular orbital. It is this orbital that contains the electrons highest in energy and so most reactive. In this orbital there is no electron density on the middle carbon; it is all on the end carbons. Hence it will be the end carbons that will react with electrophiles. This is conveniently represented by curly arrows.

![Molecular orbital diagram](image)

**A summary of the allyl anion system**

- There are no localized double and single bonds—both C–C bonds are the same and in between a double and single bond
- Both end carbons are the same
- The four electrons in the π system are spread out over all three carbon atoms. In the bonding orbital most electron density is on the central carbon but, in the nonbonding orbital, there is electron density only on the end carbons
- The electrons highest in energy and so most reactive (those in the HOMO) are to be found on the end carbons. Electrophiles will therefore react with the end carbons

Such predictions from a consideration of the molecular orbitals are confirmed both by the reactions of the allyl anion and by its NMR spectrum. It is possible to record a carbon NMR spectrum of the allyl anion directly (for example, as its lithium derivative). The spectrum shows only two signals: the middle carbon at 147 p.p.m. and the two end carbons both at 51 p.p.m.
The central carbon’s shift of 147 p.p.m. is almost typical of a normal double bond carbon whilst the end carbons’ shift is in between that of a double bond and a saturated carbon bearing a negative charge. Notice also that the central carbon in the allyl cation and the anion have almost identical chemical shifts—142 and 147 p.p.m., respectively. If anything, the anion central carbon is more deshielded. Compare this with the spectra for methyllithium and propene itself. Methyllithium shows a single peak at –15 p.p.m. and propene shows three $^{13}$C signals as indicated below.

![Chemical structures](image)

**Other allyl-like systems**

**The carboxylate anion**

You may already be familiar with one anion very much like the allyl anion—the carboxylate ion formed on deprotonating a carboxylic acid with a base. In this structure we again have a double bond adjacent to a single bond but here oxygen atoms replace two of the carbon atoms.

\[
\text{R} - \text{O} \quad \text{H} \quad \text{OH} \quad \text{R} - \text{O} \quad \text{+} \quad \text{H}_2\text{O}
\]

\[
\text{a carboxylic acid} \quad \text{a carboxylate anion}
\]

X-ray crystallography shows both carbon–oxygen bond lengths in this anion to be the same (136 pm), in between that of a normal carbon–oxygen double bond (123 pm) and single bond (143 pm). The negative charge is spread out equally over the two oxygen atoms.

![Chemical structures](image)

The electrons are delocalized over the $\pi$ system

*The structures emphasize the equivalence of the two C–O bonds and that the negative charge is spread over both oxygen atoms.*

The molecular orbital energy diagram for the carboxylate anion is the very similar to that of the allyl system. There are just two main differences.

1. The coefficients of the atomic orbitals making up the molecular orbitals will change because oxygen is more electronegative than carbon and so has a greater share of electrons
2. The absolute values of the energy levels will be different from those in the allyl system, again because of the difference in the electronegativities. Compare with the differences between the molecular orbitals for ethene and a carbonyl, p. 103

**The nitro group**

The nitro group consists of a nitrogen bonded to two oxygen atoms and a carbon (for example, an alkyl group). There are two ways of representing the structure: one using formal charges, the other using a dative bond. Notice in each case that one oxygen is depicted as being doubly bonded, the other singly bonded. Drawing both oxygen atoms doubly bonded is incorrect—*nitrogen cannot have five bonds* since this would represent ten electrons around it and there are not enough orbitals to put them in.
The problem with the two correct drawings is that they do not show the equivalence of the two N–O bonds. However, we do have an N–O double bond next to an N–O single bond which means that the negative charge is delocalized over both of the oxygen atoms. This can be shown by curly arrows.

Just to reiterate, the same molecular orbital energy diagram can be used for the allyl systems and the carboxylate and nitro groups. Only the absolute energies of the molecular orbitals are different since different elements with different electronegativities are used in each.

The amide group

The amide is a very important group in nature since it is the link by which amino acids join together to form peptides, which make up the proteins in our bodies. The structure of this deceptively simple group has an unexpected feature, which is responsible for much of the stability of proteins.

In the allyl anion, carboxylate, and nitro systems we had four electrons in the \( \pi \) system spread out over three atoms. The nitrogen in the amide group also has a pair of electrons that could conjugate with the \( \pi \) bond of the car-bonyl group. Again, for effective overlap with the \( \pi \) bond, the lone pair of electrons must be in a p orbital. This in turn means that the nitrogen must be sp\(^2\) hybridized.

In the carboxylate ion, a negative charge was shared (equally) between two oxygen atoms. In an amide there is no charge as such—the lone pair on nitrogen is shared between the nitrogen and the oxygen. However, since oxygen is more electronegative than nitrogen, it has more than its fair share of the electrons in this \( \pi \) system. (This is why the p orbital on the oxygen atom in the lowest bonding orbital shown above is slightly larger than the p orbital on the nitrogen.) The delocalization can be shown using curly arrows.

This representation suffers from the usual problems. Curly arrows show the movement of a pair of electrons. The structure on the left, therefore, suggests that electrons are flowing from the nitrogen to the oxygen. This is not true: the molecular orbital picture tells us that the electrons are unevenly distributed over the three atoms in the \( \pi \) system with a greater electron density on the oxygen. The curly arrows show us how to draw an alternative diagram. The structure on the right implies that the nitrogen’s lone pair electrons have moved completely on to the oxygen. Again this is not true; there is simply more electron density on the oxygen than on the nitrogen. The arrows are useful in that they help us to depict how the electrons are unevenly shared in the \( \pi \) system.

A better representation might be this structure. The charges in brackets indicate substantial, though not complete, charges, maybe about a half plus or minus charge. However, we cannot draw mechanisms on this structure and all these representations have their uses.
The amide is a functional group of exceptional importance so we shall look at these points in more detail.

**The structure of the amide group**

How do we know the amide group is planar? X-ray crystal structures are the simplest answer. Other techniques such as electron diffraction also show that simple (noncrystalline) amides have planar structures. N,N-dimethylformamide (DMF) is an example.

The C–N bond length to the carbonyl group is closer to that of a standard C–N double bond (127 pm) than to that of a single bond (149 pm). This partial double bond character is responsible for the restricted rotation about the C–N bond which we would expect if it were only a single bond.

The oxygen is more electron-rich than the nitrogen. Hence we might expect the oxygen rather than the nitrogen to be the site of electrophilic attack.

The amide group as a whole is made more stable as a result of the delocalization.

Let us summarize these points.
- The amide group is planar—this includes the first carbon atoms of the R groups attached to the carbonyl group and to the nitrogen atom
- The lone pair electrons on nitrogen are delocalized into the carbonyl group
- The C–N bond is strengthened by this interaction—it takes on partial double bond character. This also means that we no longer have free rotation about the C–N bond which we would expect if it were only a single bond
- The oxygen is more electron-rich than the nitrogen. Hence we might expect the oxygen rather than the nitrogen to be the site of electrophilic attack
- The amide group as a whole is made more stable as a result of the delocalization

The amide is a functional group of exceptional importance so we shall look at these points in more detail.

Proteins are composed of many amino acids joined together with amide bonds. The amino group of one can combine with the carboxylic acid group of another to give an amide. This special amide, which results from the combining of two amino acids, is known as a **peptide**—two amino acids join to form a dipeptide; many join to give a polypeptide.
The peptide unit so formed is a planar, rigid structure since there is restricted rotation about the C–N bond. This means that two isomers should be possible—a cis and a trans. It is found that nearly all the peptide units found in nature are trans. This is not surprising since the cis form is more crowded (a trans disubstituted double bond is lower in energy than a cis for the same reason).

**Protein shape and activity**

This planar, trans peptide unit poses serious limitations on the shapes proteins can adopt. Understanding the shapes of proteins is very important—enzymes, for example, are proteins with catalytic properties. Their catalytic function depends on the shape adopted: alter the shape in some way and the enzyme will no longer work.

**Reactivity of the amide group**

Just as delocalization stabilizes the allyl cation, anion, and radical, so too is the amide group stabilized by the conjugation of the nitrogen’s lone pair with the carbonyl group. This, together with the fact that the amine part is such a poor leaving group, makes the amide one of the least reactive carbonyl groups (we shall discuss this in Chapter 12).

Furthermore, the amine part of the amide group is unlike any normal amine group. Most amines are easily protonated. However, since the lone pair on the amide’s nitrogen is tied up in the π system, it is less available for protonation or, indeed, reaction with any electrophile. As a result, an amide is preferentially protonated on the oxygen atom but it is difficult to protonate even there (see next chapter, p. 201). Conjugation affects reactivity.

**The conjugation of two π bonds**

The simplest compound that can have two conjugated π bonds is butadiene. As we would now expect, this is a planar compound that can adopt two different conformations by rotating about the single bond. Rotation is somewhat restricted (around 30 kJ mol⁻¹) but nowhere near as much as in an amide (typically 60–90 kJ mol⁻¹). What do the molecular orbitals for the butadiene π system look like? The lowest-energy molecular orbital will have all the p orbitals combining in-phase. The next lowest will have one node, and then two, and the highest-energy molecular orbital will have three nodes (that is, all the p orbitals will be out-of-phase).

**Isomers of butadiene**

Butadiene normally refers to 1,3-butadiene. It is also possible to have 1,2-butadiene which is another example of an allene (p. 157).

**The molecular orbitals of butadiene**

Butadiene has two π bonds and so four electrons in the π system. Which molecular orbitals are these electrons in? Since each molecular orbital can hold two electrons, only the two molecular orbitals lowest in energy are filled. Let’s have a closer look at these orbitals. In Ψ₁, the lowest-energy bonding orbital, the electrons are spread out over all four carbon atoms (above and below the plane) in one continuous orbital. There is bonding between all the atoms. The other two electrons are in Ψ₂. This orbital has bonding interactions between carbon atoms 1 and 2, and also between 3 and 4 but an antibonding interaction between carbons 2 and 3. Overall, in both the occupied π orbitals there are
electrons between carbons 1 and 2 and between 3 and 4, but the antibonding interaction between carbons 2 and 3 in \( \Psi_2 \) partially cancels out the bonding interaction in \( \Psi_1 \). This explains why all the bonds in butadiene are not the same and why the middle bond is more like a single bond while the end bonds are double bonds. If we look closely at the coefficients on each atom in orbitals \( \Psi_1 \) and \( \Psi_2 \), it can be seen that the bonding interaction between the central carbon atoms in \( \Psi_1 \) is greater than the antibonding one in \( \Psi_2 \). Thus butadiene does have some double bond character between carbons 2 and 3, which explains why there is the slight barrier to rotation about this bond.

In our glimpse of hexatriene earlier in this chapter we saw a similar effect, which we could now interpret if we looked at all the molecular orbitals for hexatriene. We have three double bonds and two single bonds with slightly restricted rotation. Both butadiene and hexatriene have double bonds and single bond: neither compound has all its C–C bond lengths the same, yet both compounds are conjugated. What is the real evidence for conjugation? How does the conjugation show itself in the properties and reactions of these compounds? To answer these questions, we need to look again at the energy level diagram for butadiene and compare it with that of ethene. A simple way to do this is to make the orbitals of butadiene by combining the orbitals of ethene.
We have drawn the molecular orbital diagram for the π molecular orbitals of butadiene as a result of combining the π molecular orbitals of two ethene molecules. There are some important points to notice here.

- The overall energy of the two bonding butadiene molecular orbitals is lower than that of the two molecular orbitals for ethene. This means that butadiene is more thermodynamically stable than we might expect if its structure were just two isolated double bonds.
- The HOMO for butadiene is higher in energy relative to the HOMO for ethene. This means butadiene should be more reactive than ethene towards nucleophiles.
- The LUMO for butadiene is lower in energy than the LUMO for ethene. Consequently, butadiene would be expected to be more reactive towards nucleophiles than ethene.
- So whilst butadiene is more stable than two isolated double bonds, it is also more reactive (Chapter 20).

**Butadiene model**

A simple theoretical model of the butadiene system predicts the energy of the bonding ψ₁ orbital to be \([\alpha + 1.62\beta]\) and that of bonding orbital \(\psi_2\) to be \([\alpha + 0.62\beta]\). With both of these orbitals fully occupied, the total energy of the electrons is \([4\alpha + 4.48\beta]\). Remember that the energy of the bonding π molecular orbital for ethene was \([\alpha + \beta]\) (p. 152) so, if we were to have two localized π bonds (each with two electrons), the total energy would be \([4\alpha + 4\beta]\). This theory predicts that butadiene with both double bonds conjugated is lower in energy than it would be with two localized double bonds by 0.48\(\beta\). Both \(\alpha\) and \(\beta\) are negative; hence \([4\alpha + 4.48\beta]\) is lower in energy than \([4\alpha + 4\beta]\) by 0.48\(\beta\).
UV and visible spectra

In Chapter 2 we saw how, if given the right amount of energy, electrons can be promoted from a low-energy atomic orbital to a higher-energy one and how this gives rise to an atomic absorption spectrum. Exactly the same process can occur with molecular orbitals. In fact, we have already seen (p. 153) that UV light can promote an electron from the HOMO to the LUMO in a double bond.

**HOMO–LUMO gap**

Electrons can be promoted from any filled orbital to any empty orbital. The smallest energy difference between a full and empty molecular orbital is between the HOMO and the LUMO. The smaller this difference, the less energy will be needed to promote an electron from the HOMO to the LUMO: the smaller the amount of energy needed, the longer the wavelength of light needed since \( \Delta E = h\nu \).

Therefore, an important measurement is the wavelength at which a compound shows maximum absorbance, \( \lambda_{\text{max}} \). A difference of more than about 4 eV (about \( 7 \times 10^{-19} \) J) between HOMO and LUMO means that \( \lambda_{\text{max}} \) will be in the ultraviolet region (wavelength, \( \lambda < 300 \) nm). If the energy difference is between about 3 eV (about \( 4 \times 10^{-19} \) J) and 1.5 eV (about \( 3 \times 10^{-19} \) J) then \( \lambda_{\text{max}} \) will be in the visible part of the spectrum.

We have seen above that the energy difference between the HOMO and LUMO for butadiene is less than that for ethene. Therefore we would expect butadiene to absorb light of longer wavelength than ethene (the longer the wavelength the lower the energy, \( \Delta E = h\nu \)). This is found to be the case: butadiene absorbs at 215 nm compared to 185 nm for ethene. The conjugation in butadiene means it absorbs light of a longer wavelength than ethene. In fact, this is true generally.

- The more conjugated a compound is, the smaller the energy transition between its HOMO and LUMO and hence the longer the wavelength of light it can absorb. Hence UV–visible spectroscopy can tell us about the conjugation present in a molecule.
Both ethene and butadiene absorb in the far-UV region of the electromagnetic spectrum (215 nm is just creeping into the UV region) but, if we extend the conjugation further, the gap between HOMO and LUMO will eventually be sufficiently decreased to allow the compound to absorb visible light and hence be coloured. A good example is the red pigment in tomatoes we introduced at the start of the chapter. It has eleven conjugated double bonds (plus two unconjugated) and absorbs light at about 470 nm.

The colour of pigments depends on conjugation

You can see now that it is no coincidence that this compound and the two other highly conjugated compounds we met earlier, chlorophyll and β-carotene, are all highly coloured natural pigments. In fact, all dyes and pigments are highly conjugated compounds.

Every extra conjugated double bond in a system increases the wavelength of light that is absorbed. If there are fewer than about eight conjugated double bonds, the compound absorbs in
the ultraviolet and we don’t notice the difference. With more than eight conjugated double bonds, the absorption creeps into the visible and, by the time it reaches 11, the compound is red. If we wanted a blue or green compound, we should need a very large number of conjugated double bonds and such pigments do not usually rely on π bonds alone.

Transitions from bonding to antibonding π orbitals are called π → π* transitions. A much smaller energy gap is available if we use electrons in a nonbonding orbital as the electrons start off much higher in energy and can be promoted to low-lying antibonding π orbitals. We call these transitions n → π*, where the ‘n’ stands for nonbonding. It is easy to find coloured compounds throughout the whole range of wavelengths by this means. The colour of blue jeans comes from the pigment indigo. The two nitrogen atoms provide the lone pairs that can be excited into the π* orbitals of the rest of the molecule. These are low in energy because of the two carbonyl groups. Yellow light is absorbed by this pigment and indigo-blue light transmitted.

Jeans are dyed by immersion in a vat of reduced indigo, which is colourless since the conjugation is interrupted by the central single bond. When the cloth is hung up to dry, the oxygen in the air oxidizes the ‘pigment’ to indigo and the jeans turn blue. Conjugation is the key to colour.

Many conjugated compounds are yellow because, although they have their λ_max in the UV, the broad absorption tails into the visible and the compound weakly absorbs violet light making it pale yellow. An example is this imine with a long conjugated system joining the two aromatic rings together.

The imine is yellow but when it is reduced to the amine, breaking the conjugation in the middle so that the two benzene rings are no longer linked together, the result is a dark orange compound. This is rather surprising because you would normally expect the compound with the longer conjugated system to absorb at longer wavelengths. Check with the table above to see that an orange compound definitely absorbs at longer wavelengths than a yellow compound.

The answer to this paradox lies in the change of hybridization of the nitrogen atom. In the imine, the nitrogen is trigonal and the lone pair is in an sp² orbital in the plane of the conjugated system. No delocalization of the lone pair is possible and the UV absorption comes from a simple π → π* transition. When the imine is reduced, the C–N bond can rotate and the amine can be trigonal too, but with the N–H bond in the plane and the lone pair in a p orbital conjugated with the right-hand benzene ring. The absorption giving the orange colour is an n → π* transition not a π → π* transition. Even delocalization of a lone pair into one benzene ring with a nitro group can give a longer wavelength absorption than a conjugated system of bonding electrons.

Aromaticity

Let us now return to the structure of benzene. Benzene is unusually stable for an alkene and is not normally described as an alkene at all. For example, whereas normal alkenes readily react with
Bromine reacts with benzene in a substitution reaction (a bromine atom replaces a hydrogen atom), keeping the benzene structure intact. This ability to retain its ring structure through all sorts of chemical reactions is one of the important differences of benzene compared to alkenes and one that originally helped to define the class of aromatic compounds to which benzene belongs.

Cyclooctatetraene has four double bonds in a ring. What do you think its structure will be?

You will probably be surprised to find cyclooctatetraene (COT for short), unlike benzene, is not planar. Also none of the double bonds are conjugated—there are indeed alternate double and single bonds in the structure but conjugation is possible only if the \( p \) orbitals of the double bonds can overlap; here they do not. Since there is no conjugation, there are two \( C-C \) bond lengths in cyclooctatetraene—146.2 and 133.4 pm—which are typical for single and double \( C-C \) bonds. If possible, make a model of cyclooctatetraene for yourself—you will find the compound naturally adopts the shape below. This shape is often called a ‘tub’.

Chemically, cyclooctatetraene behaves like an alkene not like benzene. Bromine, for example, does not form a substitution product but an addition product. There is something strange going on here—why is benzene so different from other alkenes and why is cyclooctatetraene so different from benzene? The mystery deepens when we look at what happens when we treat cyclooctatetraene with powerful oxidizing or reducing agents.

If 1,3,5,7-tetramethylcyclooctatetraene is treated at low temperature (−78 °C) with \( \text{SbF}_5/\text{SO}_2\text{ClF} \) (strongly oxidizing conditions) a dication is formed. This cation, unlike the neutral compound, is planar and all the \( C-C \) bond lengths are the same.

**Drawing the dication**

The dication still has the same number of atoms as the neutral species only fewer electrons. Where have the electrons been taken from? The \( \pi \) system now has two electrons less. We could draw a structure showing two localized positive charges but this would not be ideal since the charge is spread over the whole ring system.
It is also possible to add electrons to cyclooctatetraene by treating it with alkali metals and a dianion results. X-ray structures reveal this dianion to be planar, again with all C–C bond lengths the same (140.7 pm). The difference between the anion and cation of cyclooctatetraene on the one hand and cyclooctatetraene on the other is the number of electrons in the π system. The cation has six π electrons, the anion has ten, but neutral cyclooctatetraene has eight.

Substituted benzene compounds, such as the one below with six silicon atoms around the edge, can also react with lithium to give a dianion. This dianion, with eight π electrons, is now no longer planar.

Treatment of benzene itself with the strongly oxidizing SbF₅/SO₂ClF reagent has no effect but it is possible to oxidize substituted derivatives. Hexakis(dimethylamino)benzene, for example, can be oxidized with iodine. Again, the resulting dication is nonplanar and all the C–C bond lengths are not the same.

Do you see a pattern forming? The important point is not the number of conjugated atoms but the number of electrons in the π system. When they have 4 or 8 π electrons, both benzene and cyclooctatetraene adopt nonplanar structures; when they have 6 or 10 π electrons, a planar structure is preferred.

If you made a model of cyclooctatetraene, you might have tried to force it to be flat. If you managed this you probably found that it didn’t stay like this for long and that it popped back into the tub shape. The strain in planar COT can be overcome by the molecule adopting the tub conformation. The strain is due to the numbers of atoms and double bonds in the ring—it has nothing to do with the number of electrons. The planar dication and dianion of COT still have this strain. The fact that these ions do adopt planar structures must mean there is some other form of stabilization that outweighs the strain of being planar. This extra stabilization is called aromaticity.

**Heats of hydrogenation of benzene and cyclooctatetraene**

It is possible to reduce unsaturated C=C double bonds using hydrogen gas and a catalyst (usually nickel or palladium) to produce fully saturated alkanes. This process is called hydrogenation and it is exothermic (that is, energy is released) since a thermodynamically more stable product, an alkane, is produced.

### Margarine manufacture

This reaction is put to good use in the manufacture of margarines. One of the ingredients in many margarines is hydrogenated vegetable oil. When polyunsaturated fats are hydrogenated they become more solid. This means that, rather than having to pour our margarine on to our toast in the morning, we can spread it. We saw the second acid in this series, linoleic acid, at the start of Chapter 2.

When cis-cyclooctene is hydrogenated, 96 kJ mol⁻¹ of energy is released. Cyclooctatetraene releases 410 kJ mol⁻¹ on hydrogenation. This value is approximately four times one double
bond’s worth, as we might expect. However, whereas the heat of hydrogenation for cyclohexene is 120 kJ mol$^{-1}$, on hydrogenating benzene, only 208 kJ mol$^{-1}$ is given out, which is much less than the 360 kJ mol$^{-1}$ that we would have predicted. This is shown in the energy level diagram below.

Benzene has six $\pi$ molecular orbitals

The difference between the amount of energy we expect to get out on hydrogenation (360 kJ mol$^{-1}$) and what is observed (208 kJ mol$^{-1}$) is about 150 kJ mol$^{-1}$. This represents a crude measure of just how extra stable benzene really is relative to what it would be like with three localized double bonds. In order to understand the origin of this stabilization, we must look at the molecular orbitals. We can think of the $\pi$ molecular orbitals of benzene as resulting from the combination of the six $p$ orbitals. We have already encountered the molecular orbital lowest in energy with all the orbitals combining in-phase.

The next molecular orbital will have one nodal plane. How can we divide up the six atoms symmetrically with one nodal plane? There are two ways depending on whether or not the nodal plane passes through a bond or an atom.

It turns out that these two different molecular orbitals both have exactly the same energy, that is, they are degenerate. This isn’t obvious from looking at them but, nevertheless, it is so.

The next molecular orbital will have two nodal planes and again there are two ways of arranging these, which lead to two degenerate molecular orbitals.
The final molecular orbital will have three nodal planes, which must mean all the $p$ orbitals combining out-of-phase. These then are the six $\pi$ molecular orbitals for benzene. We can draw an energy level diagram to represent them.

Benzene model

Whilst the HOMOs for benzene are the degenerate $\pi$ molecular orbitals ($\Psi_2$), the next molecular orbital down in energy is not actually the $\pi$ molecular orbital ($\Psi_1$). This all-bonding $\pi$ molecular orbital ($\Psi_1$) is so stable that four $\sigma$ bonding molecular orbitals actually come in between the $\pi$ molecular $\Psi_1$ and $\Psi_2$ orbitals but are not shown in this molecular orbital energy level diagram. The greatest contribution to stability comes from this lowest-energy $\pi$ bonding molecular orbital ($\Psi_1$). This allows bonding interactions between all adjacent atoms. Theory tells us that the energy of this orbital is $\alpha + 2\beta$ whilst that of the degenerate bonding $\pi$ molecular orbitals is $\alpha + \beta$. When all these bonding molecular orbitals are fully occupied, the total energy of the electrons is $6\alpha + 8\beta$, which is $2\beta$ lower in energy than we would predict for three localized double bonds. Butadiene had a theoretical stabilization energy of just $0.48\beta$ relative to two isolated double bonds so $2\beta$ is really quite significant.

The $\pi$ molecular orbitals of conjugated cyclic hydrocarbons can be easily predicted

Notice that the layout of the energy levels is a regular hexagon with its apex pointing downwards. It turns out that the energy level diagram for the molecular orbitals resulting from the combination of any regular cyclic arrangement of $p$ orbitals can be deduced from the appropriately sided polygon. If we take a regular polygon with one corner pointing downwards and draw a circle round it so that all the corners touch the circle, the energies of the molecular orbitals will be where the corners touch the circle. The circles should be of the same size and the polygons fitted inside the circle. The horizontal diameter represents the energy of a carbon $p$ orbital and so, if any energy levels are on this line, they must be nonbonding. All those below are bonding; all those above antibonding.
Notes on these energy level diagrams:

- This method predicts the energy levels for the molecular orbitals of planar, monocyclic, arrangements of identical atoms (usually all C) only
- The dashed line represents an energy level $\alpha$ and in each case the circle radius is $2\beta$
- There is always one single molecular orbital lower in energy than all the others (at energy $\alpha + 2\beta$). This is because there is always one molecular orbital where all the p orbitals combine in-phase
- If there are an even number of atoms, there is also a single molecular orbital highest in energy; otherwise there will be a pair of degenerate molecular orbitals highest in energy
- All the molecular orbitals come in degenerate pairs except the one lowest in energy and, for even-numbered systems, the one highest in energy

Now we can begin to put all the pieces together and make sense of what we know so far. Let us compare the energy level diagrams for benzene and planar cyclooctatetraene. We are not concerned with the actual shapes of the molecular orbitals involved, just the energies of them.

Benzene has six $\pi$ electrons, which means that all its bonding molecular orbitals are fully occupied giving a closed shell structure. COT, on the other hand, has eight electrons. Six of these fill up the bonding molecular orbitals but there are two electrons left. These must go into the degenerate pair of nonbonding orbitals. Hund’s rule (Chapter 4) would suggest one in each. Therefore this planar structure for COT would not have the closed shell structure that benzene has—it must either lose or gain two electrons in order to have a closed shell structure with all the electrons in bonding orbitals. This is exactly what we have already seen—both the dianion and dication are planar, allowing delocalization all over the ring, whereas neutral COT adopts a nonplanar tub shape with localized bonds.

Hückel’s rule tells us if compounds are aromatic

Using this simple method to work out the energy level diagrams for other rings, we find that there is always a single low-energy bonding orbital (composed of all p orbitals combining in-phase) and then pairs of degenerate orbitals. Since the single orbital will hold two electrons when full and the degenerate pairs four, we shall have a closed shell of electrons in these $\pi$ orbitals only when they contain $2 + 4n$ electrons ($n$ is an integer 0, 1, 2, etc.). This is the basis of Hückel’s rule.

 Analogous systems with $4n\pi$ electrons are described as anti-aromatic
Note the trans–trans–cis double bonds: all bond angles can be 120°. [20]annulene presumably could become planar (it isn’t quite) but since it is a 4n p electron system rather than a 4n + 2 system, it is not aromatic and the structure shows localized single and double bonds.

The importance of the system being monocyclic is less clear. The problem that often arises is ‘exactly how do we count the π electrons?’ Taking a simple example, should we consider naphthalene as two benzene rings joined together or as a ten π electron system?

From its chemistry, it is very clear that naphthalene is aromatic but perhaps a little less so than benzene itself. For example, naphthalene can easily be reduced to tetralin (1,2,3,4-tetrahydronaphthalene) which still contains a benzene ring. Also, in contrast to benzene, all the bond lengths in naphthalene are not the same.

Hückel’s rule is very useful and it helps us to predict and understand the aromatic stability of numerous other systems. Cyclopentadiene, for example, has two double bonds that are conjugated but the whole ring is not conjugated since there is a methylene group in the ring. However, this compound is relatively easy to deprotonate (see next chapter, p. 000) to give a very stable anion in which all the bond lengths are the same. How many electrons does this system have? Each of the double bonds contributes two electrons and the negative charge (which must be in a p orbital to complete the conjugation) contributes a further two making six altogether. The energy level diagram shows us that six π electrons completely fill the bonding molecular orbitals thereby giving a stable structure.

### Aromatic heterocyclic compounds

So far all the aromatic compounds you have seen have been hydrocarbons. However, most aromatic systems are heterocyclic—that is, involving atoms other than carbon and hydrogen. A simple example is pyridine.

In this structure a nitrogen replaces one of the CH groups in benzene. The ring still has three double bonds and thus six π electrons. Consider the structure shown below, pyrrole. This is also aromatic but how can we count six π electrons?

In the cyclopentadiene ring above, there were also two double bonds and on deprotonation one carbon could formally contribute the other two electrons needed for aromaticity. In pyrrole the nitrogen’s lone pair can make up the six π electrons needed for the system to be aromatic.

We are really just beginning to scratch the surface of aromatic chemistry. You will meet many aromatic compounds in this book; in Chapter 22 we shall look at the chemistry of benzene and in Chapters 43 and 44 we shall discuss heterocyclic aromatic compounds. We shall finish off this chapter with a few more examples of some common aromatic compounds. In each case the aromatic part of the molecule—which may be one ring or several rings—is outlined in black.
First, a compound released by many cut plants, especially grasses, with a fresh delightful smell usually called ‘new mown hay’. Coumarin is also present in some herbs such as lavender. It contains a benzene ring and an α-pyrone fused together.

Next, pirimicarb, a selective insecticide that kills sap-sucking aphid pests but does not affect the useful predators such as ladybirds (ladybugs) that eat them. It contains a pyrimidine ring—a benzene ring with two nitrogen atoms.

LSD stands for LySergic acid Diethylamide. It is the hallucinogenic drug ‘acid’. When people walk off a building claiming that they can fly, they are probably on acid. It contains an indole ring made up of a benzene ring and a pyrrole ring fused together.

The world’s best selling medicine in 1998 was Omeprazole, an antiulcer drug from Astra. It prevents excess acid in the stomach and allows the body to heal ulcers. It contains a pyridine ring and a benzimidazole ring, two aromatic heterocycles.

The drug in the news in 1999 was Viagra, Pfizer’s cure for male impotence. In the first three months after its release in 1998, 2.9 million prescriptions were issued for Viagra. It contains a simple benzene ring and a more complex heterocyclic system, which can be divided into two aromatic heterocyclic rings.
Finally, the iron compound haem, part of the haemoglobin molecule we use to carry oxygen around in our bloodstream. It contains the aromatic porphyrin ring system with its eighteen electrons arranged in annulene style. Chlorophyll, mentioned earlier in this chapter, has a similar aromatic ring system.

Problems

1. Are these molecules conjugated? Explain your answer in any reasonable way.

2. Draw a full orbital diagram for all the bonding and antibonding $\pi$ orbitals in the three-membered cyclic cation shown here. The molecule is obviously very strained. Might it survive by also being aromatic?

3. How extensive are the conjugated systems in these molecules?

4. Draw diagrams to illustrate the conjugation present in these molecules. You should draw three types of diagram: (a) conjugation arrows to give at least two different ways of representing the molecule joined by the correct ‘reaction’ arrow; (b) a diagram with dotted lines and partial charges (if any) to show the double bond and charge distribution (if any); and (c) a diagram of the
atomic orbitals that make up the lowest-energy bonding molecular orbital.

5. Which of these compounds are aromatic? Justify your answer with some electron counting. You are welcome to treat each ring separately or two or more rings together, whichever you prefer.

6. A number of water-soluble pigments in the green/blue/violet ranges used as food dyes are based on cations of the type shown here. Explain why the general structure shows such long wavelength absorption and suggest why the extra functionality (OH group and sulfonate anions) is put into ‘CI food green 4’ a compound approved by the EU for use in food under E142.

7. Turn to Chapter 1 and look at the structures of the dyes in the shaving foam described on p. 000. Comment on the structures in comparison with those in Problem 6 and suggest where they get their colour from and why they too have extra functional groups. Then turn to the beginning of Chapter 1 (p. 000) and look at the structures of the compounds in the ‘spectrum of molecules’. Can you see what kind of absorption leads to each colour? You will want to think about the conjugation in each molecule but you should not expect to correlate structures with wavelengths in any even roughly quantitative way.

8. Go through the list of aromatic compounds at the end of the chapter and see how many electrons there are in the rings taken separately or taken together (if they are fused). Are all the numbers of the \((4n + 2)\) kind?
Note from the authors to all readers

This chapter contains physical data and mathematical material that some readers may find daunting. Organic chemistry students come from many different backgrounds since organic chemistry occupies a middle ground between the physical and the biological sciences. We hope that those from a more physical background will enjoy the material as it is. If you are one of those, you should work your way through the entire chapter. If you come from a more biological background, especially if you have done little maths at school, you may lose the essence of the chapter in a struggle to understand the equations. We have therefore picked out the more mathematical parts in boxes and you should abandon these parts if you find them too alien. We consider the general principles behind the chapter so important that we are not prepared to omit this essential material but you should try to grasp the principles without worrying too much about the equations. The ideas of acidity, basicity, and $pK_a$ values together with an approximate quantitative feel for the strength and weakness of acids and bases are at least as central for biochemistry as they are for organic chemistry. Please do not be discouraged but enjoy the challenge.

Introduction

This chapter is all about acidity, basicity, and $pK_a$. Acids and bases are obviously important because many organic and biological reactions are catalysed by acids or bases, but what is $pK_a$ and what use is it? $pK_a$ tells us how acidic (or not) a given hydrogen atom in a compound is. This is useful because, if the first step in a reaction is the protonation or deprotonation of one of the reactants, it is obviously necessary to know where the compound would be protonated or deprotonated and what strength acid or base would be needed. It would be futile to use too weak a base to deprotonate a compound but, equally, using a very strong base where a weak one would do would be like trying to
crack open a walnut using a sledge hammer—you would succeed but your nut would be totally destroyed in the process.

The aim of this chapter is to help you to understand why a given compound has the \( pK_a \) that it does. Once you understand the trends involved, you should have a good feel for the \( pK_a \) values of commonly encountered compounds and also be able to predict the values for unfamiliar compounds.

Originally, a substance was identified as an acid if it exhibited the properties shown by other acids: a sour taste (the word acid is derived from the Latin *acidus* meaning ‘sour’) and the abilities to turn blue vegetable dyes red, to dissolve chalk with the evolution of gas, and to react with certain ‘bases’ to form salts. It seemed that all acids must therefore contain something in common and at the end of the eighteenth century, the French chemist Lavoisier erroneously proclaimed this common agent to be oxygen (indeed, he named oxygen from the Greek *oxus* ‘acid’ and *gennao* ‘I produce’). Later it was realized that some acids, for example, hydrochloric acid, did not contain oxygen and soon hydrogen was identified as the key species. However, not all hydrogen-containing compounds are acidic, and at the end of the nineteenth century it was understood that such compounds are acidic only if they produce hydrogen ions \( H^+ \) in aqueous solution—the more acidic the compound, the more hydrogen ions it produces. This was refined once more in 1923 by J.N. Brønsted who proposed simple definitions for acids and bases.

### Brønsted definitions of acids and bases
- An acid is a species having a tendency to lose a proton
- A base is a species having a tendency to accept a proton

## Acidity

**An isolated proton is incredibly reactive—formation of \( H_3O^+ \) in water**

Hydrochloric acid is a strong acid: the free energy \( \Delta G^\circ \) for its ionization equilibrium in water is \(-40\) kJ mol\(^{-1}\).

\[
\text{HCl (aq)} \rightleftharpoons \text{H}^+ (aq) + \text{Cl}^- (aq) \quad \Delta G^\circ_{298K} = -40 \text{ kJ mol}^{-1}
\]

Such a large negative \( \Delta G^\circ \) value means that the equilibrium lies well over to the right. In the gas phase, however, things are drastically different and \( \Delta G^\circ \) for the ionization is \(+1347\) kJ mol\(^{-1}\).

\[
\text{HCl (g)} \rightleftharpoons \text{H}^+ (g) + \text{Cl}^- (g) \quad \Delta G^\circ_{298K} = +1347 \text{ kJ mol}^{-1}
\]

This \( \Delta G^\circ \) value corresponds to 1 molecule of HCl in \(10^{240}\) being dissociated! This means that HCl does not spontaneously ionize in the gas phase—it does not lose protons at all. Why then is HCl such a strong acid in water? The key to this problem is, of course, the water. In the gas phase we would have to form an isolated proton (\( H^+ \), hydrogen ion) and chloride ion and this is energetically very unfavourable. In contrast, in aqueous solution the proton is strongly attached to a water molecule to give the very stable hydronium ion, \( H_3O^+ \), and the ions are no longer isolated but solvated. Even in the gas phase, adding an extra proton to neutral water is highly exothermic.

\[
\text{H}_2\text{O (g)} + \text{H}^+ (g) \rightarrow \text{H}_3\text{O}^+ (g) \quad \Delta H^\circ = -686 \text{ kJ mol}^{-1}
\]

In fact, an isolated proton is so reactive that it will even add on to a molecule of methane in the gas phase to give \( \text{CH}_5^+ \) in a strongly exothermic reaction (you have already encountered this species in mass spectrometry on p. 52). We are therefore extremely unlikely to have a naked proton in the gas phase and certainly never in solution. In aqueous solution a proton will be attached to a water molecule to give a hydronium ion, \( H_3O^+ \) (sometimes called a hydroxonium ion). This will be solvated just as any other cation (or anion) would be and hydrogen bonding gives rise to such exotic species as \( H_9O_4^+ \) (\( H_3O^+ \cdot 3\text{H}_2\text{O} \)) shown here.
Every acid has a conjugate base

In water, hydrogen chloride donates a proton to a water molecule to give a hydronium ion and chloride ion, both of which are strongly solvated.

\[
\text{HCl (aq) + H}_2\text{O (l)} \rightarrow \text{H}_3\text{O}^+ \text{ (aq)} + \text{Cl}^- \text{ (aq)}
\]

In this reaction water is acting as a base, according to our definition above, by accepting a proton from HCl which in turn is acting as an acid by donating a proton. If we consider the reverse reaction (which is admittedly insignificant in this case since the equilibrium lies well over to the right), the chloride ion accepts a proton from the hydronium ion. Now the chloride is acting as a base and the hydronium ion as an acid. The chloride ion is called the conjugate base of hydrochloric acid and the hydronium ion, \(\text{H}_3\text{O}^+\), is the conjugate acid of water.

For any acid and any base

\[
\text{AH} + \text{B} \rightarrow \text{BH}^+ + \text{A}^-
\]

where \(\text{AH}\) is an acid and \(\text{A}^-\) is its conjugate base and \(\text{B}\) is a base and \(\text{BH}^+\) is its conjugate acid, that is, every acid has a conjugate base associated with it and every base has a conjugate acid associated with it.

For example, with ammonia and acetic acid

\[
\text{CH}_3\text{COOH} + \text{NH}_3 \rightarrow \text{NH}_4^+ \text{CH}_3\text{COO}^-
\]

the ammonium ion, \(\text{NH}_4^+\), is the conjugate acid of the base ammonia, \(\text{NH}_3\), and the acetate ion, \(\text{CH}_3\text{COO}^-\), is the conjugate base of acetic acid, \(\text{CH}_3\text{COOH}\).

Water can behave as an acid or as a base

If a strong acid is added to water, the water acts as a base and is protonated by the acid to become \(\text{H}_3\text{O}^+\). If we added a strong base to water, the base would deprotonate the water to give hydroxide ion, \(\text{OH}^-\), and here the water would be acting as an acid. Such compounds that can act as either an acid or a base are called amphoteric.

With a strong enough acid, we can protonate almost anything and, likewise, with a strong enough base we can deprotonate almost anything. This means that, to a certain degree, all compounds are amphoteric. For example, hydrochloric acid will protonate acetic acid.

In this example acetic acid is acting as a base! Other compounds need acids even stronger than HCl to protonate them. Remember that, in chemical ionization mass spectrometry (p. 52), protonated methane, \(\text{CH}_4^+\), was used to protonate whatever sample we put in to the machine in order to give us a cation; \(\text{CH}_4^+\) is an incredibly strong acid.

The amino acids you encountered in Chapter 2 are amphoteric. Unlike water, however, these compounds have separate acidic and basic groups built into the same molecule.

When amino acids are dissolved in water, the acidic end protonates the basic end to give a species with both a positive and a negative charge on it. A neutral species that contains both a positive and a negative charge is called a zwitterion.

How the pH of a solution depends on the concentration of the acid

You are probably already familiar with the pH scale: acidic solutions all have a pH of less than 7—the lower the pH the more acidic the solution; alkaline solutions all have pHs greater than 7—the higher the pH, the more basic the solution. Finally, pH 7 is neither acidic nor alkaline but neutral.

The pH of a solution is only a measure of the acidity of the solution; it
tells us nothing about how strong one acid might be relative to another. The pH of a solution of a given acid varies with its concentration: as we dilute the solution, the acidity falls and the pH increases. For example, as we decrease the concentration of HCl in an aqueous solution from 1 to 0.1 to 0.01 to 0.001 mol dm$^{-3}$, the pH changes from 0 to 1 to 2 to 3.

What a pH meter actually measures is the concentration of hydronium ions in the solution. The scale is a logarithmic one and is defined as

$$\text{pH} = -\log([\text{H}_3\text{O}^+])$$

Our solutions of HCl above therefore have hydronium ion concentrations of $[\text{H}_3\text{O}^+] = 10^0, 10^{-1}, 10^{-2},$ and $10^{-3}$ mol dm$^{-3}$ respectively. Since the scale is logarithmic, a pH difference of 1 corresponds to a factor of 10 in hydronium ion concentration, a pH difference of 2 corresponds to a factor of 100, and so on.

The ionization of water

Pure water at 25 °C has a pH of 7.00. This means that the concentration of hydronium ions in water must be $10^{-7}$ mol dm$^{-3}$ (of course, it is actually the other way round: the hydronium ion concentration in pure water is $10^{-7}$ mol dm$^{-3}$; hence its pH is 7.00). Hydronium ions in pure water can arise only from the self-dissociation or autoprotolysis of water.

$$\text{H}_2\text{O} + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ (aq) + \text{OH}^-(aq)$$

In this reaction, one molecule of water is acting as a base, receiving a proton from the other, which in turn is acting as an acid by donating a proton. From the equation we see that, for every hydronium ion formed, we must also form a hydroxide ion and so in pure water the concentrations of hydroxide and hydronium ions are equal.

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] = 10^{-7} \text{ mol dm}^{-3}$$

The product of these two concentrations is known as the ionization constant of water, $K_W$ (or as the ionic product of water, or sometimes as the autoprotolysis constant, $K_{AP}$)

$$K_W = [\text{H}_3\text{O}^+][\text{OH}^-] = 10^{-14} \text{ mol}^2 \text{ dm}^{-6} \text{ at 25 °C}$$

This is a constant in aqueous solutions, albeit a very, very small one. This means that, if we know the hydronium ion concentration, we also know the hydroxide concentration and vice versa since the product of the two concentrations always equals $10^{-14}$.

**For example**

It is easy to work out the pH of a 0.1 M solution of sodium hydroxide, $[\text{NaOH}] = 0.1$ M

and, since the sodium hydroxide is fully ionized, $[\text{OH}^-] = 0.1$ M but $[\text{OH}^-] \times [\text{H}_3\text{O}^+] = 10^{-14}$.

So

$$[\text{H}_3\text{O}^+] = \frac{10^{-14}}{0.1} = 10^{-13} \text{ mol dm}^{-3}$$

$$\text{pH} = -\log([\text{H}_3\text{O}^+]) = -\log(10^{-13}) = 13$$

How the pH of a solution also depends on the acid in question

If we measured the pH of an aqueous solution of an organic acid and compared it to an equally concentrated solution of HCl, we would probably find the pHs different. For example, whilst 0.1M HCl has a pH of 1, the same concentration of acetic acid has a pH of 3.7 and is much less acidic. This can only mean that a 0.1M solution of acetic acid contains fewer hydronium ions than a 0.1M solution of HCl.

- Aqueous hydrochloric acid (or any strong acid) has a lower pH than an equal concentration of aqueous acetic acid (or any weak acid) because it is more fully dissociated and thereby produces more hydronium ions.

For hydrochloric acid, the equilibrium lies well over to the right: in effect, HCl is completely dissociated.

$$\text{HCl (aq)} + \text{H}_2\text{O (l)} \rightleftharpoons \text{H}_3\text{O}^+ (aq) + \text{Cl}^- (aq)$$
Acetic acid is not fully dissociated—the solution contains both acetic acid and acetate ions.

\[
\text{CH}_3\text{COOH (aq)} + \text{H}_2\text{O (l)} \rightarrow \text{CH}_3\text{COO}^- (aq) + \text{H}_3\text{O}^+ (aq)
\]

**Acids as preservatives**

Acetic acid is used as a preservative in many foods, for example, pickles, mayonnaise, bread, and fish products, because it prevents bacteria and fungi growing. However, its fungicidal nature is not due to any lowering of the pH of the foodstuff. In fact, it is the undissociated acid that acts as a bactericide and a fungicide in concentrations as low as 0.1–0.3%. Besides, such a low concentration has little effect on the pH of the foodstuff anyway.

Although acetic acid can be added directly to a foodstuff (disguised as E260), it is more common to add vinegar which contains between 10 and 15% acetic acid. This makes the product more ‘natural’ since it avoids the nasty ‘E numbers’. Actually, vinegar has also replaced other acids used as preservatives, such as propionic (propanoic) acid (E280) and its salts (E281, E282, and E283).

**The definition of p\(K_a\)**

Now we need to be clearer about ‘strong’ and ‘weak’ acids. In order to measure the strength of an acid relative to water and find out how effective a proton donor it is, we must look at the equilibrium constant for the reaction

\[
\text{AH (aq)} + \text{H}_2\text{O (l)} \rightarrow \text{H}_3\text{O}^+ (aq) + \text{A}^- (aq)
\]

The position of equilibrium is measured by the equilibrium constant for this reaction \(K_{eq}\):

\[
K_{eq} = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{AH}][\text{H}_2\text{O}]}.
\]

The concentration of water remains essentially constant (at 55.56 mol dm\(^{-3}\)) with dilute solutions of acids wherever the equilibrium may be and a new equilibrium constant, \(K_a\), is defined and called the acidity constant.

\[
K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{AH}]}
\]

Like pH, this is also expressed in a logarithmic form, p\(K_a\).

\[\text{p}K_a = -\log K_a\]

Because of the minus sign in this definition, the lower the p\(K_a\), the larger the equilibrium constant, \(K_a\), and hence the stronger the acid. The p\(K_a\) of the acid is the pH where it is exactly half dissociated. At pHs above the p\(K_a\), the acid HA exists as A\(^-\) in water; at pHs below the p\(K_a\), it exists as undissociated HA.

At pHs above the p\(K_a\) of the acid, it will also be more soluble in water. Hydrocarbons are insoluble in water—oil floats on water, for example. Unless a compound has some hydrophilic groups in it that can hydrogen bond to the water, it too will be insoluble. Ionic groups considerably increase a compound’s solubility and so the ion A\(^-\) is much more soluble in water than the undissociated acid HA. In fact water can solvate both cations and anions, unlike some of the solvents you will meet later. This means that we can increase the solubility of a neutral acid in water by increasing the proportion of its conjugate base present. All we need to do is raise the pH.

A simple example is aspirin: whilst the acid itself is not very soluble in water, the sodium salt is much more soluble (soluble aspirin is actually the sodium or calcium salt of ‘normal’ aspirin).

Conversely, if the pH of a solution is lowered, the amount of the acidic form present increases, and the solubility decreases. In the acidic environment of the stomach (around pH 1–2), soluble aspirin will be converted back to the normal acidic form and precipitate out of solution.
In the same way, organic bases such as amines can be dissolved by lowering the pH. Codeine (7,8-didehydro-4,5-epoxy-3-methoxy-17-methylmorphinan-6-ol) is a commonly used painkiller. Codeine itself is not very soluble in water but it does contain a basic nitrogen atom that can be protonated to give a more soluble salt. It is usually encountered as a phosphate salt. The structure is complex, but that doesn’t matter.

Charged compounds can be separated by acid–base extraction

Adjusting the pH of a solution often provides an easy way to separate compounds. Since weak acids form soluble anions at pHs above their $pK_a$ values, this presents us with an easy method for extracting organic acids from mixtures of other compounds. For example, if we dissolve the mixture of compounds in dichloromethane (which is immiscible with water, that is, it will not mix with water but instead forms a separate layer) and ‘wash’ this solution with aqueous sodium hydroxide, any organic acids present will be converted to their water-soluble salts and dissolve into the water layer. We have extracted the organic acids into the aqueous layer. If we then separate and acidify the aqueous layer, the acid form, being less soluble in water, will precipitate out. If the acid form has a charge and the conjugate base is neutral as with amines, for example, now the cationic acid form will be more soluble in water than the conjugate base.

### Acid–base extraction

For a neutral weak organic acid $HA$

$$HA(aq) + H_2O \rightarrow H_3O^+(aq) + A^- (aq)$$

- Anionic $A^-$ is more soluble in water than the neutral acid $HA$
- Neutral acid $HA$ is more soluble in organic solvents than anionic $A^-$

For a neutral weak organic base $B$

$$HB^-(aq) + H_2O \rightarrow H_3O^+(aq) + B(aq)$$

- The cationic acid $HB^+$ is more soluble in water than the neutral conjugate base $B$
- The neutral conjugate base, $B$ is more soluble in organic solvents than the cationic acid $HB^+$

Separating a mixture of benzoic acid ($PhCO_2H$) and toluene ($PhMe$) is easy: dissolve the mixture in $CH_2Cl_2$, add aqueous $NaOH$, shake the mixture of solutions, and separate the layers. The $CH_2Cl_2$ layer contains all the toluene. The aqueous layer contains the sodium salt of benzoic acid. Addition of $HCl$ to the aqueous layer precipitates the insoluble benzoic acid.

In the same way, any basic compounds dissolved in an organic layer could be extracted by washing the layer with dilute aqueous acid and recovered by raising the pH, which will precipitate out the less soluble neutral compound.
Whenever you do any extractions or washes in practical experiments, just stop and ask yourself: ‘What is happening here? In which layer is my compound and why?’ That way you will be less likely to throw the wrong layer (and your precious compound) away!

**Benzoic acid preserves soft drinks**

Benzoic acid is used as a preservative in foods and soft drinks (E210). Like acetic acid, it is only the acid form that is effective as a bactericide. Consequently, benzoic acid can be used as a preservative only in foodstuffs with a relatively low pH, ideally less than its $pK_a$ of 4.2. This isn’t usually a problem: soft drinks, for example, typically have a pH of 2–3. Benzoic acid is often added as the sodium salt (E211), perhaps because this can be added to the recipe as a concentrated solution in water. At the low pH in the final drink, most of the salt will be protonated to give benzoic acid proper, which presumably remains in solution because it is so dilute.

**A graphical description of the p$K_a$ of acids and bases**

For both cases, adjusting the pH alters the proportions of the acid form and of the conjugate base. The graph plots the concentration of the free acid AH (green curve) and the ionized conjugate base $A^-$ (red curve) as percentages of the total concentration as the pH is varied.

At low pH the compound exists entirely as AH and at high pH entirely as $A^-$. At the $pK_a$ the concentration of each species, AH and $A^-$, is the same. At pHs near the $pK_a$ the compound exists as a mixture of the two forms.

**An acid’s $pK_a$ depends on the stability of its conjugate base**

HCl is a much stronger acid than acetic acid: the $pK_a$ of HCl is around –7 compared to 4.76 for acetic acid. This tells us that in solution $K_a$ for hydrogen chloride is $10^7$ mol dm$^{-3}$ whilst for acetic acid it is only $10^{-4.76} = 1.74 \times 10^{-5}$ mol dm$^{-3}$. Why are the equilibria so different? Why does hydrogen chloride fully dissociate but acetic acid do so only partially?

$$\text{HCl (aq) + H}_2\text{O (l)} \rightleftharpoons \text{H}_3\text{O}^+ (aq) + \text{Cl}^- (aq) \quad K_a = 10^7$$

$$\text{CH}_3\text{COOH (aq) + H}_2\text{O (l)} \rightleftharpoons \text{H}_3\text{O}^+ (aq) + \text{CH}_3\text{COO}^- (aq) \quad K_a = 1.74 \times 10^{-5}$$

The answer must have something to do with the conjugate base $A^-$ of each acid HA, since this is the only thing that varies from one acid to another. In both the equilibria above, water acts as a base by accepting a proton from the acid. For the hydrochloric acid equilibrium in the reverse direction, the chloride ion is not a strong enough base to deprotonate the hydronium ion. Acetate, on the other hand, is easily protonated by $\text{H}_3\text{O}^+$ to give neutral acetic acid, which means that acetate must be a stronger base than chloride ion.

- **Acid and conjugate base strength**

  - The stronger the acid HA, the weaker its conjugate base, $A^-$
  - The stronger the base $A^-$, the weaker its conjugate acid AH
An alternative way of looking at this is that chloride ion is much happier being a chloride ion than acetate is being an acetate ion: the chloride ion is fundamentally more stable than is the acetate ion.

A close look at Table 8.1 for there are some interesting points to notice.

- Look at the acids themselves—we have neutral, cationic, and even anionic acids.
- Notice the range of different elements carrying the negative charge of the conjugate bases—we have iodine, chlorine, oxygen, sulfur, nitrogen, and carbon and many more are possible.
- Most importantly, notice the vast range of \( pK_a \) values: from around –10 to 50. This corresponds to a difference of \( 10^{30} \) in the equilibrium constants and these are by no means the limits. Other compounds or intermediates can have \( pK_a \) values even greater or less than these.

That the difference in \( pK_a \) gives the log of the equilibrium constant can easily be shown by considering, as an example, the equilibrium for the reaction between hydrogen sulfate and acetate.

\[
\text{HSO}_4^- + \text{CH}_3\text{COO}^- \rightleftharpoons \text{CH}_3\text{COOH(aq)} + \text{SO}_4^{2-}
\]

\[
K_{eq} = \frac{[\text{CH}_3\text{COOH}(aq)] \cdot [\text{SO}_4^{2-}]}{[\text{HSO}_4^-] \cdot [\text{CH}_3\text{COO}^-]} \]

The equilibrium constant for this reaction is simply the \( K_a \) for the hydrogen sulfate equilibrium divided by the \( K_a \) for the acetic acid equilibrium.

\[
K_{eq} = K_a(\text{HSO}_4^-) \times \frac{1}{K_a(\text{CH}_3\text{COOH})} = \frac{10^{-2}}{10^{-4.8}} = 600
\]

This tells us in our case that, if we mixed sodium hydrogen sulfate and sodium acetate in water, we would end up with mainly sodium sulfate and acetic acid, the equilibrium constant for the reaction above being approximately 600.

For example, hydrogen iodide has a very low \( pK_a \) of –10. This means that HI is a strong enough acid to protonate most things. Its conjugate base, iodide ion, is therefore not very basic at all—in fact, we very rarely think of it as a base—it will not deprotonate anything. A very powerful base is methyllithium, MeLi. Here we effectively have CH₃⁻ (but see Chapter 9), which can accept a proton to become neutral methane, CH₄. Methane is therefore the conjugate acid in this case. Clearly, methane isn’t at all acidic—it's \( pK_a \) is about 48.

Table 8.1 gives a list of compounds and their approximate \( pK_a \) values.

Over the next few pages we shall be considering the reasons for these differences in acid strength but we are first going to consider the simple consequences of mixing acids or bases of different strength.

The difference in \( pK_a \) values tells us the equilibrium constant between two acids or bases.

If we have a mixture of two bases in a pot and we throw in a few protons, where will the protons end up? Clearly, this depends on the relative strengths of the bases—if they are equally strong, then the protons will be shared between them equally. If one base is stronger than the other, then this base will get more than its fair share of protons. If we put into our pot not two bases but one base and an acid, then it’s exactly the same as putting in two bases and then adding some protons—the protons end up on the strongest base. Exactly how the protons are shared depends on the difference in strengths of the two bases, which is related to the difference in the \( pK_a \)s of their conjugate acids.

In a mixture of two acids or two bases:

- The ratio of \( K_a \) values gives us an indication of the equilibrium constant for the reaction between a base and an acid.
- The difference in \( pK_a \)s gives us the log of the equilibrium constant.

As an example, let us look at a method for acetylation of aromatic amines in aqueous solution. This reaction has a special name—the Lumière–Barbier method. We shall consider the acetylation of aniline PhNH₂ (a basic aromatic amine) using acetic anhydride. The procedure for this reaction is as follows.

1. Dissolve one equivalent of aniline in water to which one equivalent of hydrochloric acid has been added.

Aniline is not soluble in water to any significant degree. This isn’t surprising as aniline is just a hydrophobic hydrocarbon with an amine group. The HCl (\( pK_a = –7 \)) protonates the aniline (\( pK_a \) of the conjugate acid of aniline is 4.6) to give the hydrochloride. Now we have a salt that is very soluble in water.

![Diagram of aniline and anilinium ion](image)

- Aniline: insoluble in water
- Anilinium ion: soluble in water
2 Warm to 50°C and add 1.2 equivalents of acetic anhydride followed by 1.2 equivalents of aqueous sodium acetate solution.

The acetic anhydride could be attacked by either the water, the acetate, or by aniline itself. Aniline is much more nucleophilic than the other two nucleophiles but only aniline itself can attack the anhydride: protonated aniline has no lone pair and is not nucleophilic. This, then, is the role of the sodium acetate—to act as a base and deprotonate the aniline hydrochloride. The pK_a of the aniline hydrochloride and acetic acid are about the same, around 4.7. An equilibrium will be set up to give some neutral aniline which will then attack the acetic anhydride and form the amide.

---

3 Cool in ice and filter off crystals of product, acetalanilide.

The product is insoluble in water and, because it is an amide, is much less basic than aniline (pK_a of conjugate acid < 0) and so is not protonated to give a water-soluble salt.

---

**More from pK_a's: Calculating the pK_a values for water acting as a base and as an acid**

The material in this box is quite mathematical and may be skipped if you find it too alien.

**How easy is it to protonate or deprotonate water?**

All our reactions so far have been in water and it is easy to forget that water itself also competes for protons. If, for example, we have both sulfuric acid H_2SO_4 and hydrochloric acid HCl in aqueous solution, hydrochloric acid with its lower pK_a (~3), hydrogen sulfate HSO_4^-: both acids will protonate water instead. So water is a stronger base than either chloride or hydrogen sulfate ions. In fact, we can work out the pK_a for the protonation of water.

We want to answer the questions: 'How easy is it to protonate water? What strength of acid do we need?'

Look at this simple reaction:

\[
\text{H}_2\text{O}^- + \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+ + \text{OH}^- \]

Obviously, the equilibrium constant for the equation above will be 1 since both sides of the equation are the same. But we don’t use normal equilibrium constants — we use the acidity constant, K_a, which is slightly different.

Remember that this is actually the normal equilibrium constant for the reaction multiplied by [H_2O] = 55.56, the ‘concentration’ of water. This is normally useful in that it cancels out the [H_2O] term in the denominator but not in this case.

Here we have

\[
K_a = K_{eq} \times [H_2O] = \frac{[H_3O^+][OH^-]}{[H_2O][H_3O^+]} \times [H_2O] = 55.56
\]

so the pK_a for the protonation of water is: pK_a(H_3O^+) = -log(55.56) = -1.74.

The pK_a also equals the pH when we have equal concentrations of acid and conjugate base. A solution would be quite acidic if exactly half of the number of water molecules present were hydronium ions— its pH would be -1.74.

So with water acting as a base

\[
\text{AH} + \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+ + \text{A}^-
\]

It is clear that for any acid with a lower pK_a than -1.74, the equilibrium will lie over to the right.

- **Acids with a lower pK_a than -1.74 will protonate water completely**

We can also work out the pK_a for water acting as an acid. Now the equilibrium is

\[
\text{H}_2\text{O}^- + \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+ + \text{OH}^-
\]

Going through the same calculations as before, we find

\[
K_a = K_{eq} \times [H_2O] = \frac{[H_3O^+][OH^-]}{[H_2O][H_3O^+]} \times [H_2O] = 55.56
\]

\[
K_{eq} = 10^{-14} \times \frac{1.80 \times 10^{-16}}{55.56} = 1.80 \times 10^{-16}
\]

so the pK_a for the deprotonation of water is: pK_a(H_2O^-) = -log(1.80 × 10^{-16}) = 15.74.

This means that, if we put in water a base whose conjugate acid’s pK_a is greater than 15.74, it will simply be protonated by the water and give an equivalent amount of hydroxide ions.

- **Bases B whose conjugate acid HB has a higher pK_a than 15.74 will deprotonate water completely**

---

Any sharp-eyed readers may notice an inconsistency in the statement that the pK_a equals the pH when we have equal concentrations of acid and conjugate base. If, when [A^-] = [AH], the pK_a = pH, then the pK_a for water equals the pH when [H_2O] = [H_3O^+]. We assume that [H_2O] is constant at 55.56 mol dm^{-3} and so [H_3O^+] must also equal 55.56 mol dm^{-3} and hence pH = pK_a = -log(55.56). This assumption cannot be valid here: rather [H_2O] + [H_3O^+] should equal approximately 55.56 mol dm^{-3}.

---
The choice of solvent limits the $pK_a$ range we can use

In water, our effective $pK_a$ range is only –1.74 to 15.74, that is, it is determined by the solvent. This is known as the *levelling effect* of the solvent. This is an important point. It means that, if we want to remove the proton from something with a high $pK_a$, say 25–30, it would be impossible to do this in water since the strongest base we can use is hydroxide. If we do need a stronger base than OH$^-$, we must use a different solvent system.

For example, if we wanted to deprotonate ethyne (acetylene, $pK_a$ 25), then hydroxide (the strongest base we could have in aqueous solution, $pK_a$ 15.7) would establish an equilibrium where only 1 in $10^{15.7}/10^{25}$ ethyne molecules were deprotonated. This means about 1 in 2 billion of our ethyne molecules will be deprotonated at any one time. Since, no matter what base we dissolve in water, we will only at best get hydroxide ions, this is the best we could do in water. So, in order to deprotonate ethyne to any appreciable extent, we must use a different solvent that does not have a $pK_a$ less than 25. Conditions often used to do this reaction are sodium amide (NaNH$_2$) in liquid ammonia.

Using the $pK_a$s of NH$_3$ (ca, 33) and ethyne (25) we would predict an equilibrium constant for this reaction of $10^8$ ($10^{-25}/10^{-33}$)—well over to the right. Amide ions can be used to deprotonate alkynes.

Because the $pK_a$ values for very strong acids and bases are so hard to determine, you will find that they often differ in different texts—sometimes the values are no better than good guesses! However, while the absolute values may differ, the relative values (which is the important thing because we need only a rough guide) are usually consistent.
different compounds and, if you know what factors affect them, it will make it much easier to predict an approximate $pK_a$ value, or at least understand why a given compound has the $pK_a$ value that it does.

A number of factors affect the strength of an acid, $AH$.

\[
AH \text{ (solvent)} \quad \leftrightarrow \quad A^- \text{ (solvent)} + H^+ \text{ (solvent)}
\]

These include:

1. **Intrinsic stability of the conjugate base, anion $A^-$.** Stability can arise, for example, by having the negative charge on an electronegative atom or by spreading the charge over other groups. Either way, the more 'stable' the conjugate base, the less basic it will be and so the stronger the acid.

2. **Bond strength $A$–$H$.** Clearly, the easier it is to break this bond, the stronger the acid.

3. **The solvent.** The better the solvent is at stabilizing the ions formed, the easier it is for the reaction to occur.

### Acid strength

- The most important factor in the strength of an acid is the stability of the conjugate base—the more stable the conjugate base, the stronger the acid.
- An important factor in the stability of the conjugate base is which element the negative charge is on—the more electronegative the element, the more stable the conjugate base.

### The negative charge on an electronegative element stabilizes the conjugate base

The $pK_a$ values for second row hydrides $CH_4$, $NH_3$, $H_2O$, and HF are about 48, 33, 16, and 3, respectively. This trend is due to the increasing electronegativities across the period: $F^-$ is much more stable than $CH_3^-$, because fluorine is much more electronegative than carbon.

### Weak $A$–$H$ bonds make stronger acids

However, on descending group VII (group 17), the $pK_a$ values for HF, HCl, HBr, and HI decrease in the order 3, –7, –9, and –10. Since the electronegativities decrease on descending the group we might expect an increase in $pK_a$. The decrease observed is actually due to the weakening bond strengths on descending the group and to some extent the way in which the charge can be spread over the increasingly large anions.

### Delocalization of the negative charge stabilizes the conjugate base

The acids HClO, HClO$_2$, HClO$_3$, and HClO$_4$ have $pK_a$ values 7.5, 2, –1, and about –10, respectively. In each case the acidic proton is on an oxygen attached to chlorine, that is, we are removing a proton from the same environment in each case. Why then is perchloric acid, HClO$_4$, some 17 orders of magnitude stronger in acidity than hypochlorous acid, HClO? Once the proton is removed, we end up with a negative charge on oxygen. For hypochlorous acid, this is localized on the one oxygen. With each successive oxygen, the charge can be more delocalized, and this makes the anion more stable. For example, with perchloric acid, the negative charge can be delocalized over all four oxygen atoms.

\[
\text{BH} \quad \leftrightarrow \quad \text{etc.}
\]

That the charge is spread out over all the oxygen atoms equally is shown by electron diffraction studies: whereas perchloric acid has two types of Cl–O bond, one 163.5 pm and the other three 140.8 pm long, in the perchlorate anion all Cl–O bond lengths are the same, 144 pm, and all O–Cl–O bond angles are 109.5°.
Similar arguments explain the $pK_a$s for other oxygen acids, for example, ethanol ($pK_a$, 15.9), acetic acid (4.8), and methane sulfonic acid (−1.9). In ethoxide, the negative charge is localized on one oxygen atom, whilst in acetate the charge is delocalized over two oxygens and in methane sulfonate it is spread over three oxygens.

In phenol, PhOH, the OH group is directly attached to a benzene ring. On deprotonation, the negative charge can again be delocalized, not on to other oxygens but this time on to the aromatic ring itself.

The effect of this is to stabilize the phenoxide anion relative to the conjugate base of cyclohexanol where no delocalization is possible and this is reflected in the $pK_a$s of the two compounds: 10 for phenol but 16 for cyclohexanol.

### Get a feel for $pK_a$s!

Notice that these oxygen acids have $pK_a$s that conveniently fall in units of 5 (approximately).

The same delocalization of charge can stabilize anions derived from deprotonating carbon acids. These are acids where the proton is removed from carbon rather than oxygen and, in general, they are weaker than oxygen acids because carbon is less electronegative. If the negative charge can be delocalized on to more electronegative atoms such as oxygen or nitrogen, the conjugate base will be stabilized and hence the acid will be stronger.

Table 8.2 shows a selection of carbon acids with their conjugate bases and $pK_a$s. In each case the proton removed is shown in black.
It isn’t necessary for a group to be conjugated in order to spread the negative charge: any group that withdraws electrons will help to stabilize the conjugate base and therefore increase the strength of the acid. Some examples are shown below for both oxygen and carbon acids.

**Picric acid is a very acidic phenol**

Electron-withdrawing effects on aromatic rings will be covered in more detail in Chapter 22 but for the time being note that electron-withdrawing groups can considerably lower the $pK_a$s of substituted phenols and carboxylic acids, as illustrated by picric acid.

2, 4, 6-Trinitrophenol’s more common name, picric acid, reflects the strong acidity of this compound ($pK_a 0.7$ compared to phenol’s 10.0). Picric acid used to be used in the dyeing industry but is little used now because it is also a powerful explosive (compare its structure with that of TNT!).
Electron withdrawal in these molecules is the result of σ bond polarization from an inductive effect (Chapter 5). The electrons in a σ bond between carbon and a more electronegative element such as N, O, or F will be unevenly distributed with a greater electron density towards the more electronegative atom. This polarization is passed on more and more weakly throughout the carbon skeleton. The three fluorine atoms in CF3H reduce the pKₐ to 26 from the 48 of methane, while the nine fluorines in (CF₃)₃CH reduce the pKₐ still further to 10.

Such inductive effects become less significant as the electron-withdrawing group gets further away from the negative charge as is shown by the pKₐs for these chlorobutanoic acids: 2-chloro acid is significantly stronger than butanoic acid but by the time the chlorine atom is on C4, there is almost no effect.

Hybridization can also affect the pKₐ

The hybridization of the orbital from which the proton is removed also affects the pKₐ. Since s orbitals are held closer to the nucleus than are p orbitals, the electrons in them are lower in energy, that is, more stable. Consequently, the more s character an orbital has, the more tightly held are the electrons in it. This means that electrons in an sp orbital (50% s character) are lower in energy than those in an sp² orbital (33% s character), which are, in turn, lower in energy than those in an sp³ orbital (25% s character). Hence the anions derived from ethane, ethene, and ethyne increase in stability in this order and this is reflected in their pKₐs. Cyanide ion, −CN, with an electronegative element as well as an sp hybridized anion, is even more stable and HCN has a pKₐ of about 10.

Highly conjugated carbon acids

If we can delocalize the negative charge of a conjugate anion on to oxygen, the anion is more stable and consequently the acid is stronger. Even delocalization on to carbon alone is good if there is enough of it, which is why some highly delocalized hydrocarbons have remarkably low pKₐs for hydrocarbons. Look at this series.
Increasing the number of phenyl groups decreases the pK\(_a\)—this is what we expect, since we can delocalize the charge over all the rings. Notice, however, that each successive phenyl ring has less effect on the pK\(_a\); the first ring lowers the pK\(_a\) by 8 units, the second by 7, and the third by only 1 unit. In order to have effective delocalization, the system must be planar (Chapter 7). Three phenyl rings cannot arrange themselves in a plane around one carbon atom because the ortho-hydrogens clash with each other (they want to occupy the same space) and the compound actually adopts a propeller shape where each phenyl ring is slightly twisted relative to the next.

Even though complete delocalization is not possible, each phenyl ring does lower the pK\(_a\) because the sp\(^2\) carbon on the ring is electron-withdrawing. If we force the system to be planar, as in the compounds below, the pK\(_a\) is lowered considerably.

**The ‘Fmoc’ protecting group**

Sometimes in organic chemistry, when we are trying to do a reaction on one particular functional group, another group in the molecule may also react with the reagents, often in a way that we do not want. If a compound contains such a vulnerable group, we can ‘protect’ it by first converting it into a different less reactive group that can easily be converted back to the group that we want later. An example of such a ‘protecting group’ is the Fmoc group used (for example, as the chloride, X = Cl) to protect amines or alcohols.

The protecting group is removed using a base. This works because of the acidity of the proton in position 9 on the fluorene ring. Removal of that proton causes a breakup of the molecule with the release of the amine at the end.

We saw in Chapter 7 how some compounds can become aromatic by gaining or losing electrons. Cyclopentadiene is one such compound, which becomes aromatic on deprotonation. The stability gained in becoming aromatic is reflected in the compound’s pK\(_a\).
Compare the pK\textsubscript{a} of cyclopentadiene with that of cycloheptatriene. Whilst the anion of the former has 6 \(\pi\) electrons (which makes it isoelectronic with benzene), the anion of the latter has 8 \(\pi\) electrons. Remember that on p. 176 we saw how 4\(n\) \(\pi\) electrons made a compound anti-aromatic? The cycloheptatrienyl anion does have 4\(n\) \(\pi\) electrons but it is not anti-aromatic because it isn’t planar. However, it certainly isn’t aromatic either and its pK\textsubscript{a} of around 36 is about the same as that of propene. This contrasts with the cyclopropenyl anion, which must be planar since any three points define a plane. Now the compound is anti-aromatic and this is reflected in the very high pK\textsubscript{a} (about 62). Other compounds may become aromatic on losing a proton. We looked at fluorene a few pages back: now you will see that fluorene is acidic because its anion is aromatic (14 \(\pi\) electrons).

The more stabilized the conjugate base, \(A^-\), the stronger is the acid, HA. Ways to stabilize \(A^-\) include:

- Having the charge on an electronegative element
- Delocalizing the negative charge over other carbon atoms, or even better, over more electronegative atoms
- Spreading out the charge over electron-withdrawing groups by the polarization of \(\sigma\) bonds (inductive)
- Having the negative charge in an orbital with more s character
- Becoming aromatic

Electron-donating groups decrease acidity

All of the substituents in the examples above have been electron-withdrawing and have helped to stabilize the negative charge of the conjugate base, thereby making the acid stronger. What effect would electron-donating groups have? As you would expect, these destabilize the conjugate base because, instead of helping to spread out the negative charge, they actually put more in. The most common electron-donating groups encountered in organic chemistry are the alkyl groups. These are weakly electron-releasing (p. 416).

The anions are also stabilized by solvation. Solvation is reduced by increasing the steric hindrance around the alkoxide.
Although to a lesser extent than amides (p. 165), the ester group is also stabilized by conjugation. In this case, the ‘ethoxide part’ of the ester is electron-releasing. This explains the $pK_a$ values shown below.

**Oxygen acids and carbon acids** are by far the most important examples you will encounter and by now you should have a good understanding of why their $pK_a$ values are what they are. Before we move on to bases, it would be worthwhile to remind you how different nitrogen acids are from oxygen acids, since the conjugate bases of amines are so important. The $pK_a$ of ammonia is much greater than the $pK_a$ of water (about 33 compared with 15.74). This is because oxygen is more electronegative than nitrogen and so can stabilize the negative charge better. A similar trend is reflected in the $pK_a$s of other nitrogen compounds, for example, in the amide group. Whilst the oxygen equivalent of an amide (a carboxylic acid) has a low $pK_a$, a strong base is needed to deprotonate an amide. Nevertheless, the carbonyl group of an amide does lower the $pK_a$ from that of an amine (about 30) to around 17. It’s not surprising, therefore, that the two carbonyl groups in an imide lower the $pK_a$ still further, as in the case of phthalimide. Amines are not acidic, amides are weakly acidic (about the same as alcohols), and imides are definitely acidic (about the same as phenols).

**Basicity**

A base is a substance that can accept a proton by donating a pair of electrons. We have already encountered some—for example, ammonia, water, the acetate anion, and the methyl anion. The question we must now ask is: how can we measure a base’s strength? To what extent does a base attract a proton? We hope you will realize that we have already addressed this problem by asking the same question from a different viewpoint: to what extent does a protonated base want to keep its proton? For example if we want to know which is the stronger base—formate anion or acetylide anion—we look up the $pK_a$s for their conjugate acids. We find that the $pK_a$ for formic acid (HCO$_2$H) is 3.7, whilst the $pK_a$ for ethyne (acetylene) is around 25. This means that ethyne is much more reluctant to part with its proton, that is, acetylide is much more basic than formate. This is all very well for anions—we simply look up the $pK_a$ value for the neutral conjugate acid, but what if we want to know the basicity of ammonia? If we look up the $pK_a$ for ammonia we find a value around 33 but this is the value for deprotonating neutral ammonia to give the amide ion, NH$_2$.
If we want to know the *basicity* of ammonia, we must look up the $pK_a$ of its conjugate acid, the ammonium cation, $\text{NH}_4^+$, protonated ammonia. Its $pK_a$ is 9.24 which means that ammonia is a weaker base than hydroxide—the $pK_a$ for water (the conjugate acid of hydroxide) is 15.74 (p. 190). Now we can summarize the states of ammonia at different pH values.

### Scales for basicity—$pK_B$ and $pK_{aH}$

The material in this box is quite mathematical and may be skipped if you find it too alien. It is often convenient to be able to refer to the basicity of a substance directly. In some texts a different scale is used, $pK_B$. This is derived from considering how much hydroxide ion a base forms in water rather than how much hydronium ion the conjugate acid forms.

For the $pK_B$ scale:

$$\text{B(aq)} + \text{H}_2\text{O} \rightleftharpoons \text{OH}^-\text{(aq)} + \text{BH}^+(\text{aq})$$

$$K_B = \frac{[\text{OH}^-][\text{BH}^+]}{[\text{B}]}$$

Hence

$$pK_B = -\log(K_B)$$

For the $pK_{aH}$ scale:

$$\text{BH}^+(\text{aq}) + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+(\text{aq}) + \text{B(aq)}$$

$$K_A = \frac{[\text{H}_3\text{O}^+][\text{B}]}{[\text{BH}^+]}$$

Hence

$$pK_A = -\log(K_A)$$

Just as in the acid $pK_a$ scale, the lower the $pK_a$, the stronger the acid, in the basic $pK_B$ scale, the lower the $pK_B$, the stronger the base. The two scales are related: the product of the equilibrium constants simply equals the ionic product of water.

$$K_B \times K_A = \frac{[\text{OH}^-][\text{BH}^+][\text{H}_3\text{O}^+][\text{B}]}{[\text{B}][\text{BH}^+]}$$

$$= [\text{OH}^-][\text{H}_3\text{O}^+] = K_W = 10^{-14}$$

that is,

$$pK_A + pK_B = pK_w = 14$$

There is a separate scale for bases, but it seems silly to have two different scales, the basic $pK_B$ and the familiar $pK_a$, when one will do and so we will stick to $pK_a$.

However, to avoid any misunderstandings that can arise from amphoteric compounds like ammonia, whose $pK_a$ is around 33, we will either say:

- The $pK_a$ of ammonia’s conjugate acid is 9.24 or, more concisely,
- The $pK_{aH}$ of ammonia is 9.24 (where $pK_{aH}$ simply means the $pK_a$ of the conjugate acid)

### What factors affect how basic a compound is?

This really is the same as the question we were asking about the strength of an acid—the more ‘stable’ the base, the weaker it is. The more accessible the electrons are, the stronger the base is. Therefore a negatively charged base is more likely to pick up a proton than a neutral one; a compound in which the negative charge is delocalized is going to be less basic than one with a more concentrated, localized charge, and so on. We have seen that carboxylic acids are stronger acids than simple alcohols because the negative charge formed once we have lost a proton is delocalized over two oxygens in the carboxylate but localized on just one oxygen for the alkoxide. In other words, the alkoxide is a stronger base because its electrons are more available to be protonated. Since we have already considered anionic bases, we will now look in more detail at neutral bases.

![The most important factor in the strength of a base is which element the lone pair (or negative charge) is on. The more electronegative the element, the tighter it keeps hold of its electrons, and so the less available they are to accept a proton, and the weaker is the base.](image)
This explains why ammonia is $10^{10}$ times more basic than water: since oxygen is more electronegative than nitrogen, its lone pair is lower in energy. In other words, the oxygen atom in water wants to keep hold of its electrons more than the nitrogen in ammonia does and is therefore less likely to donate them to a proton. The $pK_a$ for ammonia (that is, the $pK_a$ for ammonium ion) is 9.24 whilst the $pK_a$ for water (the $pK_a$ for hydronium ion) is −1.74. Nitrogen bases are the strongest neutral bases commonly encountered by the organic chemist and so we will pay most attention to these in the discussion that follows.

**Neutral nitrogen bases**

Ammonia is the simplest nitrogen base and has a $pK_a$ of 9.24. Any substituent that increases the electron density on the nitrogen therefore raises the energy of the lone pair thus making it more available for protonation and increasing the basicity of the amine (larger $pK_a$). Conversely, any substituent that withdraws electron density from the nitrogen makes it less basic (smaller $pK_a$).

**Effects that increase the electron density on nitrogen**

We can increase the electron density on nitrogen either by attaching an electron-releasing group or by conjugating the nitrogen with an electron-donating group. The simplest example of an electron-releasing group is an alkyl group (p. 416). If we successively substitute each hydrogen in ammonia by an electron-releasing alkyl group, we should increase the amine’s basicity. The $pK_a$ values for various mono-, di-, and trisubstituted amines are shown in Table 8.4.

Points to notice in Table 8.4:

- All the amines have $pK_a$s greater than that of ammonia (9.24)
- All the primary amines have approximately the same $pK_a$ (about 10.7)
- All the secondary amines have $pK_a$s that are slightly higher
- Most of the tertiary amines have $pK_a$s lower than those of the primary amines

The first point indicates that our prediction that replacing the hydrogens by electron-releasing alkyl groups would increase basicity was correct. A strange feature though is that, whilst substituting one hydrogen of ammonia increases the basicity by more than a factor of ten (one $pK_a$ unit), substituting two has less effect and in the trisubstituted amine the $pK_a$ is actually lower. So far we have only considered one cause of basicity, namely, the availability of the lone pair but the other factor, the stabilization of the resultant positive charge formed on protonation, is also important. Each successive alkyl group does help stabilize the positive charge because it is electron-releasing but there is another stabilizing effect—the solvent. Every hydrogen attached directly to nitrogen will be hydrogen bonded with solvent water and this also helps to stabilize the charge: the more hydrogen bonding, the more stabilization. The observed basicity therefore results from a combination of effects: (1) the increased availability of the lone pair and the stabilization of the resultant positive charge, which increases with successive replacement of hydrogen atoms by alkyl groups; and (2) the stabilization due to solvation, an important part of which is due to hydrogen bonding and this effect decreases with increasing numbers of alkyl groups.

**Gas phase acidity**

If we look at the $pK_a$ values in the gas phase, we can eliminate the hydrogen bonding contribution and we find the basicity increases in the order we expect, that is, tertiary > secondary > primary.

Introducing alkyl groups is the simplest way to increase the electron density on nitrogen but there are other ways. Conjugation with an electron-donating group produces even stronger bases (p. 202) but we could also increase the electron density by using elements such as silicon. Silicon is more...
electropositive than carbon, that is, it pushes more electron density on to carbon. This extra donation of electrons also means that the silicon compound has a higher pK\textsubscript{aH} value than its carbon analogue since the nitrogen’s lone pair is higher in energy.

The pK\textsubscript{aH}s of some amines in which the nitrogen is attached either directly or indirectly to an electron-withdrawing group are shown below. We should compare these values with typical values of about 11 for simple primary and secondary amines.

The strongly electron-withdrawing CF\textsubscript{3} and CCl\textsubscript{3} groups have a large effect when they are on the same carbon atom as the NH\textsubscript{2} group but the effect gets much smaller when they are even one atom further away. Inductive effects fall off rapidly with distance.

If the lone pair itself is in an sp\textsuperscript{2} or an sp orbital, it is more tightly held (the orbital is lower in energy) and therefore much harder to protonate. This explains why the lone pair of the nitrile group is not at all basic and needs a strong acid to protonate it.

The low pK\textsubscript{aH} of aniline (PhNH\textsubscript{2}), 4.6, is partly due to the nitrogen being attached to an sp\textsuperscript{2} carbon but also because the lone pair can be delocalized into the benzene ring. In order for the lone pair to be fully conjugated with the benzene ring, the nitrogen would have to be sp\textsuperscript{2} hybridized with the lone pair in the p orbital. This would mean that both hydrogens of the NH\textsubscript{2} group would be in the same plane as the benzene ring but this is not found to be the case. Instead, the plane of the NH\textsubscript{2} group is about 40\textdegree away from the plane of the ring. That the lone pair is partially conjugated into the ring is shown indirectly by NMR shifts and by the chemical reactions that aniline undergoes. Notice
that, when protonated, the positive charge cannot be delocalized over the benzene ring and any stabilization derived from the lone pair in unprotonated aniline being delocalized into the ring is lost.

Amides are weak bases protonated on oxygen

In contrast to aromatic amines, the amide group is completely planar (p. 165) with the nitrogen sp² hybridized and its lone pair in the p orbital, thereby enabling it to overlap effectively with the carbonyl group.

This delocalization ‘ties up’ the lone pair and makes it much less basic: the p\(K_a\) for an amide is typically between 0 and −1. Because of the delocalization amides are not protonated on nitrogen.

Protonation at nitrogen would result in a positive charge on the nitrogen atom. Since this is adjacent to the carbonyl, whose carbon is also electron-deficient, this is energetically unfavourable. Protonation occurs instead on the carbonyl oxygen atom. We can draw the mechanism for this using either a lone pair on oxygen or on nitrogen.

Furthermore, if the amide were protonated at nitrogen, the positive charge could not be delocalized on to the oxygen but would have to stay localized on the nitrogen. In contrast, when the amide is protonated on the oxygen atom, the charge can be delocalized on to the nitrogen atom making the cation much more stable. We can see this if we draw delocalization arrows on the structures in the green box.
Amidines are stronger bases than amides or amines

An amidine is the nitrogen equivalent of an amide—a $\text{C}=\text{NH}$ group replaces the carbonyl. Amidines are much more basic than amides, the $pK_{a\text{H}}$s of amidines are larger than those of amides by about 13 so there is an enormous factor of $10^{13}$ in favour of amidines. In fact, they are among the strongest neutral bases.

An amidine has two nitrogen atoms that could be protonated—one is $\text{sp}^3$ hybridized, the other $\text{sp}^2$ hybridized. We might expect the $\text{sp}^3$ nitrogen to be more basic but protonation occurs at the $\text{sp}^2$ nitrogen atom. This happens because we have the same situation as with an amide: only if we protonate on the $\text{sp}^2$ nitrogen can the positive charge be delocalized over both nitrogens. We are using both lone pairs when we protonate on the $\text{sp}^2$ nitrogen.

The electron density on the $\text{sp}^2$ nitrogen in an amidine is increased through conjugation with the $\text{sp}^3$ nitrogen. The delocalized amidinium cation has identical C–N bond lengths and a positive charge shared equally between the two nitrogen atoms. It is like a positively charged analogue of the carboxylate ion.

**Amidine bases**

Two frequently used amidine bases are DBN (1,5-diazacyclo[3.4.0]nonene-5) and DBU (1,8-diazacyclo[5.4.0]undecene-7). They are easier to make, more stable, and less volatile than simpler amidines.

Guanidines are very strong bases

Even more basic is guanidine, $pK_{a\text{H}}$ 13.6, nearly as strong a base as NaOH! On protonation, the positive charge can be delocalized over three nitrogen atoms to give a very stable cation. All three nitrogen lone pairs cooperate to donate electrons but protonation occurs, as before, on the $\text{sp}^2$ nitrogen atom.

This time the resulting guanidinium ion can be compared to the very stable carbonate dianion. All three C–N bonds are the same length in the guanidinium ion and each nitrogen atom has the same charge (about one-third positive). In the carbonate dianion, all three C–O bonds are the same length and each oxygen atom has the same charge (about two-thirds negative as it is a dianion).

Imidazoline is a simple cyclic amidine and its $pK_{a\text{H}}$ value is just what we expect, around 11. Imidazole, on the other hand, is less basic ($pK_{a\text{H}}$ 7.1) because both nitrogens are attached to an electron-withdrawing $\text{sp}^2$ carbon. However, imidazole, with its two nitrogen atoms, is more basic than pyridine ($pK_{a\text{H}}$ 5.2) because pyridine only has one nitrogen on which to stabilize the positive charge.
Both imidazole and pyridine are aromatic—they are flat, cyclic molecules with 6 \( \pi \) electrons in the conjugated system (p. 177). Imidazole has one lone pair that is and one that is not involved in the aromaticity (Chapter 43).

Protonation occurs on the nitrogen atom having the sp\(^2\) lone pair because both lone pairs contribute and the resulting delocalized cation is still aromatic. Pyridine is also protonated on its sp\(^2\) lone pair (it is the only one it has!) and the pyridinium ion is also obviously aromatic—it still has three conjugated \( \pi \) bonds in the ring.

This contrasts to pyrrole in which the lone pair on the only nitrogen atom is needed to complete the six aromatic \( \pi \) electrons and is therefore delocalized around the ring. Protonation, if it occurs at all, occurs on carbon rather than on nitrogen since the cation is then delocalized. But the cation is no longer aromatic (there is a saturated CH\(_2\) group interrupting the conjugation) and so pyrrole is not at all basic (\( pK_{a,H} \) about \(-4\)).

**Neutral oxygen bases**

We have already seen that water is a much weaker base than ammonia because oxygen is more electronegative and wants to keep hold of its electrons (p. 199). Oxygen bases in general are so much weaker than their nitrogen analogues that we don’t regard them as bases at all. It is still important to know the \( pK_{a,H} \)s of oxygen compounds because the first step in many acid-catalysed reactions is protonation at an oxygen atom. Table 8.6 gives a selection of \( pK_{a,H} \)s of oxygen compounds.

All the same factors of electron donation and withdrawal apply to oxygen compounds as well as to nitrogen compounds, but the effects are generally much less pronounced because oxygen is so electronegative. In fact, most oxygen compounds have $pK_a$'s around -7, the notable exception being the amide, which, because of the electron donation from the nitrogen atom, has a $pK_a$ around -0.5 (p. 201). They are all effectively nonbasic and strong acids are needed to protonate them.

$pK_a$ in action—the development of the drug cimetidine

The development of the anti-peptic ulcer drug cimetidine gives a fascinating insight into the important role of $pK_a$ in chemistry. Peptic ulcers are a localized erosion of the mucous membrane, resulting from overproduction of gastric acid in the stomach. One of the compounds that controls the production of the acid is histamine. (Histamine is also responsible for the symptoms of hay fever and allergies.)

Histamine works by binding into a receptor in the stomach lining and stimulating the production of acid. What the developers of cimetidine at SmithKline Beecham wanted was a drug that would bind to these receptors without activating them and thereby prevent histamine from binding but not stimulate acid secretion itself. Unfortunately, the antihistamine drugs successfully used in the treatment of hay fever did not work—a different histamine receptor was involved. Notice that cimetidine and histamine both have an imidazole ring in their structure. This is not coincidence—cimetidine’s design was centred around the structure of histamine.

In the body, most histamine exists as a salt, being protonated on the primary amine and the early compounds modelled this. The guanidine analogue was synthesized and tested to see if it had any antagonistic effect (that is, if it could bind in the histamine receptors and prevent histamine binding). It did bind but unfortunately it acted as an agonist rather than an antagonist and stimulated acid secretion rather than blocking it. Since the guanidine analogue has a $pK_a$ even greater than histamine (about 14.5 compared to about 10), it is effectively all protonated at physiological pH.

Table 8.6 (continued)
The agonistic behaviour of the drug clearly had to be suppressed. The thought occurred to the SmithKline Beecham chemists that perhaps the positive charge made the compound agonistic, and so a polar but much less basic compound was sought. Eventually, they came up with burimamide. The most important change is the replacement of the C=NH in the guanidine compound by C=S. Now instead of a guanidine we have a thiourea which is much less basic. (Remember that amidines, p. 202, are very basic but that amides aren’t? The thiourea is like the amide in that the sulfur withdraws electrons from the nitrogens.) The other minor adjustments, increasing the chain length and adding the methyl group on the thiourea, further increased the efficacy.

The new compound was a fairly good antagonist (that is, bound in the receptors and blocked histamine) but more importantly shown no agonistic behaviour at all. The compound was such a breakthrough that it was given a name, ‘burimamide’, and even tested in man. Burimamide was good, but unfortunately not good enough—it couldn’t be given orally. A rethink was needed and this time attention was focused on the imidazole ring.

The pK_aH of the imidazole ring in burimamide is significantly greater than that in histamine: the longer alkyl group in burimamide is electron-donating and raises the pK_aH of the ring. In histamine, on the other hand, the positive charge of the protonated amine withdraws electrons and decreases the pK_aH. This means, of course, that there will be a greater proportion of protonated imidazole (imidazolium cation) in burimamide and this might hinder effective binding in the histamine receptor site. So the team set out to lower the pK_aH of the imidazole ring. It was known that a sulfur occupies just about the same space as a methylene group, –CH_2–, but is more electron-withdrawing. Hence ‘thiaburimamide’ was synthesized.

In turns out that one tautomer of the imidazole ring binds better than the other (and much better than the protonated form). The introduction of a methyl group on the ring was found to increase the proportion of this tautomer and did indeed improve binding to the histamine receptor, even though the pK_aH of the ring was raised because of the electron-donating character of the methyl group.
The new drug, metiamide, was ten times more effective than burimamide when tested in man. However, there was an unfortunate side-effect: in some patients, the drug caused a decrease in the number of white blood cells, leaving the patient open to infection. This was eventually traced back to the thiourea group. The sulfur had again to be replaced by oxygen, to give a normal urea and, just to see what would happen, by nitrogen to give another guanidine.

Neither was as effective as metiamide but the important discovery was that the new guanidine no longer showed the agonistic effects of the earlier guanidine. Of course, the guanidine would also be protonated so we had the same problem we had earlier—how to decrease the $pK_a$ of the guanidine. A section of this chapter considered the effect of electron-withdrawing groups on $pK_a$ and showed that they reduce the $pK_{aH}$ and make a base less basic. This was the approach now adopted—the introduction of electron-withdrawing groups on to the guanidine to lower its $pK_{aH}$. Table 8.7 shows the $pK_{aH}$s of various substituted guanidines.

Clearly, the cyano- and nitro-substituted guanidines would not be protonated at all. These were synthesized and found to be just as effective as metiamide but without the nasty side-effects. Of the two, the cyanoguanidine compound was slightly more effective and this was developed and named ‘cimetidine’.

The development of cimetidine by Smith, Kline, and French from the very start of the project up to its launch on the market took thirteen years. This enormous effort was well rewarded—Tagamet (the trade name of the drug cimetidine) became the best-selling drug in the world and the first to gross more than one billion dollars per annum. Thousands of ulcer patients worldwide no longer had to suffer pain, surgery, or even death. The development of cimetidine followed a rational approach based on physiological and chemical principles and it was for this that one of the scientists involved, Sir James Black, received a share of the 1988 Nobel Prize for Physiology or Medicine. None of this would have been possible without an understanding of $pK_a$s.
1. If you wanted to separate a mixture of naphthalene, pyridine, and \( p \)-toluic acid, how would you go about it? All three compounds are insoluble in water.

2. In the separation of benzoic acid from toluene we suggested using NaOH solution. How concentrated a solution would be necessary to ensure that the pH was above the \( pK_a \) of benzoic acid (\( pK_a \approx 4.2 \))? How would you estimate how much solution to use?

3. What species would be present if you were to dissolve this hydroxy-acid in: (a) water at pH 7; (b) aqueous alkali at pH 12; or (c) a concentrated solution of a mineral acid?

4. What would you expect to be the site of (a) protonation and (b) deprotonation if the compounds below were treated with an appropriate acid or base. In each case suggest a suitable acid or base for both purposes.

5. Suggest what species would be formed by each of these combinations of reagents. You are advised to use \( pK_a \) values to help you and to beware of some cases where ‘no change’ might be the answer.

6. What is the relationship between these two molecules? Discuss the structure of the anion that would be formed by the deprotonation of each compound.

7. What species would be formed by treating this compound with: (a) one equivalent; (b) two equivalents of NaNH\(_2\) in liquid ammonia?

8. The carbon NMR spectra of these compounds could be run in D\(_2\)O under the conditions shown. Why were these conditions necessary and what spectrum would you expect to observe?

9. The phenols shown here have approximate \( pK_a \) values of 4, 7, 9, 10, and 11. Suggest with explanations which \( pK_a \) value belongs to which phenol.

10. Discuss the stabilization of the anions formed by the deprotonation of (a) and (b) and the cation formed by the protonation of (c). Consider delocalization in general and the possibility of aromaticity in particular.
11. The pKₐ values for the amino acid cysteine are 1.8, 8.3, and 10.8. Assign these pKₐ values to the functional groups in cysteine and draw the structure of the molecule in aqueous solution at the following pHs: 1, 5, 9, and 12.

12. Explain the variations in the pKₐ values for these carbon acids.

13. Explain the various pKₐ values for these derivatives of the naturally occurring amino acid glutamic acid. Say which pKₐ belongs to which functional group and explain why they vary in the different derivatives.

14. Neither of these methods of making pentan-1,4-diol will work. Explain why not—what will happen instead?
Using organometallic reagents to make C–C bonds

Introduction

In Chapters 2–8 we covered basic chemical concepts, which mostly fall under the headings ‘structure’ (Chapters 2–4 and 7) and ‘reactivity’ (Chapters 5, 6, and 8). These concepts are the bare bones supporting all of organic chemistry, and now we shall start to put flesh on these bare bones. In Chapters 9–23 we will tell you about the most important classes of organic reaction in more detail.

One of the things organic chemists do, for all sorts of reasons, is to make molecules. And making organic molecules means making C–C bonds. In this chapter we are going to look at one of the most important ways of making C–C bonds: using organometallics, such as organolithiums and Grignard reagents, and carbonyl compounds. We will consider reactions such as these.

The organometallic reagents act as nucleophiles towards the electrophilic carbonyl group, and this is the first thing we need to discuss: why are organometallics nucleophilic? We then move on to, firstly, how to make organometallics, then to the sort of electrophiles they will react with, and then finally to the sort of molecules we can make with them.

Organometallic compounds contain a carbon–metal bond

The polarity of a covalent bond between two different elements is determined by electronegativity. The more electronegative an element is, the more it attracts the electron density in the bond. So the
greater the difference between the electronegativities, the greater the difference between the attraction for the bonding electrons, and the more polarized the bond becomes. In the extreme case of complete polarization, the covalent bond ceases to exist and is replaced by electrostatic attraction between ions of opposite charge. We discussed this in Chapter 4 (p. 000), where we considered the extreme cases of bonding in NaF.

When we discussed (in Chapter 6) the electrophilic nature of carbonyl groups we saw that their reactivity is a direct consequence of the polarization of the carbon–oxygen bond towards the more electronegative oxygen, making the carbon a site for nucleophilic attack. In organolithium compounds and Grignard reagents the key bond bond is polarized in the opposite direction—towards carbon—making carbon a nucleophilic centre. This is true for most organometallics because, as you can see from this edited version of the periodic table, metals (such as Li, Mg, Na, K, Ca, and Al) all have lower electronegativity than carbon.

The orbital diagram—the kind you met in Chapter 4—represents the C–Li bond in methyl-lithium in terms of a sum of the atomic orbitals of carbon and lithium. Remember that, the more
electronegative an atom is, the lower in energy its atomic orbitals are (p. 000). The filled C–Li σ orbital that arises is closer in energy to the carbon’s sp³ orbital than to the lithium’s 2s orbital, so we can say that the carbon’s sp³ orbital makes a greater contribution to the C–Li σ bond and that the C–Li bond has a larger coefficient on carbon. Reactions involving the filled σ orbital will therefore take place at C rather than Li. The same arguments hold for the C–Mg bond of Grignard reagents.

We can also say that, because the carbon’s sp³ orbital makes a greater contribution to the C–Li σ bond, the σ bond resembles a filled C sp³ orbital—in other words it resembles a lone pair on carbon. This is a useful idea because it allows us to think about the way in which methyl-lithium reacts—as though it were an ionic compound Me⁻Li⁺—and you may sometimes see MeLi or MeMgCl represented in mechanisms as Me⁻.

The true structure of organolithiums and Grignard reagents is rather more complicated!

Even though these organometallic compounds are extremely reactive with water and oxygen, and have to be handled under an atmosphere of nitrogen or argon, a number have been studied by X-ray crystallography in the solid state and by NMR in solution. It turns out that they generally form complex aggregates with two, four, six, or more molecules bonded together, often with solvent molecules. In this book we shall not be concerned with these details, and it will suffice always to represent organometallic compounds as simple monomeric structures.

Making organometallics

How to make Grignard reagents

Grignard reagents are made by reacting magnesium turnings with alkyl halides in ether solvents to form solutions of alkylmagnesium halide. Iodides, bromides, and chlorides can be used, as can both aryl and alkyl halides, though they cannot contain any functional groups that would react with the Grignard reagent once it is formed. Here are some examples.

You have already met cyanide (p. 000), a carbon nucleophile that really does have a lone pair on carbon. Cyanide’s lone pair is stabilized by being in a lower-energy sp orbital (rather than sp³) and by having the electronegative nitrogen atom triply bonded to the carbon.

Carbon atoms that carry a negative charge, for example Me⁻, are known as carbanions.

The reaction scheme is easy enough to draw, but what is the mechanism? Overall it involves an insertion of magnesium into the new carbon–halogen bond. There is also a change in oxidation state of the magnesium, from Mg(0) to Mg(II). The reaction is therefore known as an oxidative insertion or oxidative addition, and is a general process for many metals such as Mg, Li (which we meet shortly), Cu, and Zn.

The mechanism of the reaction is not completely understood but a possible (but probably not very accurate) way of writing the mechanism is shown here: the one thing that is certain is that the first interaction is between the metal and the halogen atom.

Making organometallics

How to make Grignard reagents

Grignard reagents are made by reacting magnesium turnings with alkyl halides in ether solvents to form solutions of alkylmagnesium halide. Iodides, bromides, and chlorides can be used, as can both aryl and alkyl halides, though they cannot contain any functional groups that would react with the Grignard reagent once it is formed. Here are some examples.

You have already met cyanide (p. 000), a carbon nucleophile that really does have a lone pair on carbon. Cyanide’s lone pair is stabilized by being in a lower-energy sp orbital (rather than sp³) and by having the electronegative nitrogen atom triply bonded to the carbon.

Carbon atoms that carry a negative charge, for example Me⁻, are known as carbanions.

The reaction scheme is easy enough to draw, but what is the mechanism? Overall it involves an insertion of magnesium into the new carbon–halogen bond. There is also a change in oxidation state of the magnesium, from Mg(0) to Mg(II). The reaction is therefore known as an oxidative insertion or oxidative addition, and is a general process for many metals such as Mg, Li (which we meet shortly), Cu, and Zn.

The mechanism of the reaction is not completely understood but a possible (but probably not very accurate) way of writing the mechanism is shown here: the one thing that is certain is that the first interaction is between the metal and the halogen atom.
The reaction takes place not in solution but on the surface of the metal, and how easy it is to make a Grignard reagent can depend on the state of the surface—how finely divided the metal is, for example. Magnesium is usually covered by a thin coating of magnesium oxide, and Grignard formation generally requires ‘initiation’ to allow the metal to come into contact with the alkyl halide. Initiation can be accomplished by adding a small amount of iodine or 1,2-diodoethane, or by using ultrasound to dislodge the oxide layer. The ether solvent is essential for Grignard formation because (1) ethers (unlike, say, alcohols or dichloromethane) will not react with Grignards and, more importantly, (2) only in ethers are Grignard reagents soluble. In Chapter 5 you saw how triethylamine forms a complex with the Lewis acid BF₃, and much the same happens when an ether meets a metal ion such as magnesium or lithium: the metals are Lewis-acidic because they have empty orbitals (2p in the case of Li and 3p in the case of Mg) that can accept the lone pair of the ether.

**How to make organolithium reagents**

Organolithium compounds may be made by a similar oxidative insertion reaction from lithium metal and alkyl halides. Each inserting reaction requires two atoms of lithium and generates one equivalent of lithium halide salt. As with Grignard formation, there is really very little limit on the types of organolithium that can be made this way.

![Diagram of organolithium reagents]

**Some Grignard and organolithium reagents are commercially available**

Most chemists (unless they were working on a very large scale) would not usually make the simpler organolithiums or Grignard reagents by these methods, but would buy them in bottles from chemical companies (who, of course, do use these methods). The table lists some of the most important commercially available organolithiums and Grignard reagents.

**Organometallics as bases**

Organometallics need to be kept absolutely free of moisture—even moisture in the air will destroy them. The reason is that they react very rapidly and highly exothermically with water to produce
alkanes. Anything that can protonate them will do the same thing. If we represent these protonation reactions slightly differently, putting the products on the left and the starting materials (represented, just for effect, as ‘carbanions’) on the right, you can see that they are acid–base equilibria from the last chapter. The organometallic acts as a base, and is protonated to form its conjugate acid—methane or benzene in these cases.

\[
\text{Li}^+ \text{Me} + \text{H}^+ \rightarrow \text{Me}^- + \text{Li}^+ \\
\text{BrMgBr} + \text{Ph} + \text{H}^+ \rightarrow \text{Ph}^- + \text{Br}^+ + \text{Mg}^2+
\]

\[pK_a = 43 \]

\[pK_a = 48 \]

The equilibria lie vastly to the left: the \(pK_a\) values indicate that methane and benzene are extremely weak acids and that methylithium and phenylmagnesium bromide must therefore be extremely strong bases. Some of the most important uses of organolithiums—butyllithium, in particular—are as bases and, because they are so strong, they will deprotonate almost anything. That makes them very useful as reagents for making other organolithiums.

### Making organometallics by deprotonating alkynes

In Chapter 8 (p. 000) we talked about how hybridization affects acidity. Alkynes, with their C–H bonds formed from sp orbitals, are the most acidic of hydrocarbons, with \(pK_a\)s of about 25. They can be deprotonated by more basic organometallics such as butyllithium or ethylmagnesium bromide. Alkynes are sufficiently acidic to be deprotonated even by nitrogen bases, and another common way of deprotonating alkynes is to use NaNH (sodium amide), obtained by reacting sodium with liquid ammonia. An example of each is shown here: we have chosen to represent the alkynyllithium and alkynylmagnesium halide as organometallics and the alkynyl sodium as an ionic salt. Propyne and acetylene are gases, and can be bubbled through a solution of the base.

\[
\text{CH}_2=\text{CH}^- + \text{Li}^- \rightarrow \text{Li}^+ \text{CH}_2=\text{CH}^- \\
\text{CH}_2=\text{CH}^- + \text{Mg}^2+ \rightarrow \text{Mg}^2+ \text{CH}_2=\text{CH}^- \\
\text{CH}_2=\text{CH}^- + \text{Na}^+ \text{NH}_2^- \rightarrow \text{Na}^+ \text{CH}_2=\text{CH}^- + \text{NH}_3
\]

The metal derivatives of alkynes can be added to carbonyl electrophiles as in the following examples. The first (we have reminded you of the mechanism for this) is the initial step of an important synthesis of the antibiotic, erythronolide A, and the second is the penultimate step of a synthesis of the widespread natural product, farnesol.
Making organometallics by deprotonating aromatic rings: ortholithiation

Look at the reaction below: in some ways it is quite similar to the ones we have just been discussing. Butyllithium deprotonates an sp² hybridized carbon atom to give an aryllithium. It works because the protons attached to sp² carbons are more acidic than protons attached to sp³ carbons (though they are a lot less acidic than alkyne protons).

But there is another factor involved as well. There has to be a functional group containing oxygen (sometimes nitrogen) next to the proton to be removed. This functional group ‘guides’ the butyllithium, so that it attacks the adjacent protons. It does this by forming a complex with the Lewis-acidic lithium atom, much as ether solvents dissolve Grignard reagents by complexing their Lewis-acidic metal ions. This mechanism means that it is only the protons ortho to the functional group that can be removed, and the reaction is known as an ortholithiation.

The terms ortho, meta, and para were defined on p. 000.
The example below shows an organolithium formed by ortholithiation being used to make a new C–C bond. Here it is a nitrogen atom that directs attack of the butyllithium.

Ortholithiation is useful because the starting material does not need to contain a halogen atom. But it is much less general than the other ways we have told you about for making organolithiums, because there are rather tight restrictions on what sorts of groups the aromatic ring must carry.

Fredericamycin

Fredericamycin is a curious aromatic compound extracted in 1981 from the soil bacterium *Streptomyces griseus*. It is a powerful antibiotic and antitumour agent, and its structure is shown below. The first time it was made in the laboratory, in 1988, the chemists in Boston started their synthesis with three consecutive lithiation reactions: two are ortholithiations, and the third is slightly different. You needn’t be concerned about the reagents that react with the organolithiums; just look at the lithiation reactions themselves. In each one, an oxygen atom (colour-coded green) directs a strongly basic reagent to remove a nearby proton (colour-coded black). As it happens, none of the steps uses *n*-BuLi itself, but instead its more reactive cousins, sec-BuLi and tert-BuLi (see the table on p. 000). The third lithiation step uses a different kind of base, made by deprotonating an amine ($pK_a$ about 35). The yellow proton removed in this third lithiation is more acidic because it is next to an aromatic ring (p. 000).
## Halogen–metal exchange

Deprotonation is not the only way to use one simple organometallic reagent to generate another more useful one. Organolithiums can also remove halogen atoms from alkyl and aryl halides in a reaction known as halogen–metal exchange. Look at this example and you will immediately see why.

The bromine and the lithium simply swap places. As with many of these organometallic processes, the mechanism is not altogether clear, but can be represented as a nucleophilic attack on bromine by the butyllithium. But why does the reaction work? The key, again, is $pK_a$. The reaction works because the organolithium that is formed (phenyllithium, which protonated would give benzene, $pK_a$ about 43) is less basic (more stable) than the organolithium we started with (BuLi, which protonated would give butane, $pK_a$ about 50). The following reactions are also successful halogen–metal exchanges, and in each case the basicity of the organolithium decreases.

$$\text{Bu}^+\text{Li}^- + \text{BuBr} \rightarrow \text{Ph}^-\text{Li} + \text{Bu}^-\text{Br}$$

Iodides, bromides, and chlorides can all be used, but the reactions are fastest with iodides and bromides. In fact, halogen–metal exchange can be so fast that, at very low temperature (−100 °C and below), it is even occasionally possible to use compounds containing functional groups that would otherwise react with organolithiums, such as esters and nitro compounds.

---

**Fenarimol**

Fenarimol is a fungicide that works by inhibiting the fungus’s biosynthesis of important steroid molecules. It is made by reaction of a diarylketone with an organolithium derived by halogen–metal exchange.
Transmetallation

Organolithiums can be converted to other types of organometallic reagents by **transmetallation**—simply treating with the salt of a less electropositive metal. The more electropositive lithium goes into solution as an ionic salt, while the less electropositive metal (magnesium and cerium in these examples) takes over the alkyl group.

But why bother? Well, the high reactivity—and in particular the basicity—of organolithiums, which we have just been extolling, sometimes causes unwanted side-reactions. You saw in Chapter 8 that protons next to carbonyl groups are moderately acidic ($pK_a$ about 20), and because of this organolithiums occasionally act as bases towards carbonyl compounds instead of as nucleophiles. Organoceriums, for example, are rather less basic, and may give higher yields of the nucleophilic addition products than organolithiums or Grignard reagents.

Acidic protons were a major problem in several syntheses of the anticancer compounds, daunorubicin and adriamycin, which start with a nucleophilic addition to a ketone with a pair of particularly acidic protons. Organolithium and organomagnesium compounds remove these pro-
tons rather than add to the carbonyl group, so some Japanese chemists turned to organocerium compounds. They made ethynylcerium dichloride \((\text{HC}=\text{CCeCl}_2)\) by deprotonating acetylene, and then transmetallating with cerium trichloride. They found that it reacted with the ketone to give an 85% yield of the alcohol they wanted.

Using organometallics to make organic molecules

Now that you have met all of the most important ways of making organometallics (summarized here as a reminder), we shall move on to consider how to use them to make molecules: what sorts of electrophiles do they react with and what sorts of products can we expect to get from their reactions? Having told you how you can make other organometallics, we shall really be concerned for the rest of this chapter only with Grignard reagents and organolithiums. In nearly all of the cases we shall talk about, the two classes of organometallics can be used interchangeably.

- **Ways of making organometallics**
  - Oxidative insertion of Mg into alkyl halides
  - Oxidative insertion of Li into alkyl halides
  - Deprotonation of alkynes
  - Ortholithiation of functionalized benzene rings
  - Halogen-metal exchange
  - Transmetallation

Making carboxylic acids from organometallics and carbon dioxide

Carbon dioxide is a carbonyl compound, and it is an electrophile. It reacts slowly with water, for example, to form the unstable compound carbonic acid—you can think of this as a hydration reaction of a carbonyl group.
Carbon dioxide reacts with organolithiums and Grignard reagents to give carboxylate salts. Protonating the salt with acid gives a carboxylic acid with one more carbon atom than the starting organometallic. The reaction is usually done by adding solid CO₂ to a solution of the organolithium in THF or ether, but it can also be done using a stream of dry CO₂ gas.

The examples below show the three stages of the reaction: (1) forming the organometallic; (2) reaction with the electrophile (CO₂); and (3) the acidic work-up or quench, which protonates the product and destroys any unreacted organometallic left over at the end of the reaction. The three stages of the reaction have to be monitored carefully to make sure that each is finished before the next is begun—in particular it is absolutely essential that there is no water present during either of the first two stages—water must be added only at the end of the reaction, when the organometallic has all been consumed by reaction with the electrophile. You may occasionally see schemes written out without the quenching step included—but it is nonetheless always needed.

**Methicillin synthesis**

Methicillin is an important antibiotic compound because it works even against bacteria that have developed resistance to penicillin, whose structure is quite similar. It can be made from an acid obtained by reaction of carbon dioxide with an organolithium. In this case the organolithium is made by an ortholithiation reaction of a compound with two oxygen atoms that direct removal of the proton in between them.

**Making primary alcohols from organometallics and formaldehyde**

You met formaldehyde, the simplest aldehyde, in Chapter 6, where we discussed the difficulties of using it in anhydrous reactions: it is either hydrated or a polymer (paraformaldehyde, (CH₂O)ₙ) and, in order to get pure, dry formaldehyde, it is necessary to heat (‘crack’) the polymer to
decompose it. But formaldehyde is a remarkably useful reagent for making primary alcohols, in other words, alcohols that have just one carbon substituent attached to the hydroxy-bearing C atom. Just as carbon dioxide adds one carbon and makes an acid, formaldehyde adds one carbon and makes an alcohol.

In the next examples, formaldehyde makes a primary alcohol from two deprotonated alkynes. The second reaction here (for which we have shown organolithium formation, reaction, and quench simply as a series of three consecutive reagents) forms one of the last steps of the synthesis of *Cecropia* juvenile hormone whose structure you met right at the beginning of the chapter.

Secondary and tertiary alcohols: which organometallic, which aldehyde, which ketone?

Aldehydes and ketones react with Grignard or organolithium reagents to form secondary and tertiary alcohols, respectively, and some examples are shown with the general schemes here.
To make any secondary alcohol, however, there is often a choice of two possible routes, depending on which part of the molecule you choose to make the organometallic and which part you choose to make the aldehyde. For example, the first example here shows the synthesis of a secondary alcohol from isopropylmagnesium chloride and acetaldehyde. But it is equally possible to make this same secondary alcohol from isobutyraldehyde and methylithium or a methylmagnesium halide. Indeed, back in 1912, when this alcohol was first described in detail, the chemists who made it chose to start with acetaldehyde, while in 1983, when it was needed as a starting material for a synthesis, it was made from isobutyraldehyde. Which way is better? The 1983 chemists probably chose the isobutyraldehyde route because it gave a better yield. But, if you were making a secondary alcohol for the first time, you might just have to try both in the lab and see which one gave a better yield. Or you might be more concerned about which uses the cheaper, or more readily available, starting materials—this was probably behind the choice of methylmagnesium chloride and the unsaturated aldehyde in the second

Flexible alcohol synthesis

As an illustration of the flexibility available in making secondary alcohols, one synthesis of bongkrekic acid, a highly toxic compound that inhibits transport across certain membranes in the cell, required both of these (very similar) alcohols. The chemists making the compound at Harvard University chose to make each alcohol from quite different starting materials: an unsaturated aldehyde and an alkyn-containing organolithium in the first instance, and an alkyn-containing aldehyde and vinyl magnesium bromide in the second.
example. Both can be bought commercially, while the alternative route to this secondary alcohol would require a vinyllithium or vinylmagnesium bromide reagent that would have to be made from a vinyl halide, which is itself not commercially available, along with difficult-to-dry acetaldehyde.

With tertiary alcohols, there is even more choice. The last example in the box is a step in a synthesis of the natural product, nerolidol. But the chemists in Paris who made this tertiary alcohol could in principle have chosen any of these three routes.

three routes to a tertiary alcohol

Note we have dropped the aqueous quench step from these schemes to avoid cluttering them.

Only the reagents in orange are commercially available, but, as it happens, the green Grignard reagent can be made from an alkyl bromide, which is itself commercially available, making the route on the left the most reasonable.

Now, do not be dismayed! We are not expecting you to remember a chemical catalogue and to know which compounds you can buy and which you can’t. All we want you to appreciate at this stage is that there are usually two or three ways of making any given secondary or tertiary alcohol, and you should be able to suggest alternative combinations of aldehyde or ketone and Grignard reagent that will give the same product. You are not expected to be able to assess the relative merits of the different possible routes to a compound. That is a topic we leave for a much later chapter on retrosynthetic analysis, Chapter 30.

Ketones by oxidation of secondary alcohols

Tertiary alcohols can be made from ketones, and secondary ones from aldehydes, but we should now show you that ketones can be made from secondary alcohols by an oxidation reaction. There are lots of possible reagents, but a common one is an acidic solution of chromium trioxide. We will look in much more detail at oxidation later, when we will discuss the mechanism of the reaction, but for now take it from us that secondary alcohols give ketones on treatment with CrO₃. Note that you can’t oxidize tertiary alcohols (without breaking a C–C bond). The link between secondary alcohols and ketones means that the ketones needed for making tertiary alcohols can themselves ultimately be made by addition of organometallics to carbonyl compounds. Here, for example, is a sequence of reactions leading to a compound needed to make the drug viprostol.

Ketones

\[
\begin{align*}
\text{Oxidation} & \quad \text{CrO}_3 \\
\text{R}^1 & \quad \text{R}^2 \\
\text{CHO} & \quad \text{R}^1 \text{R}^2
\end{align*}
\]
We finish this chapter with some brief words about the mechanism of the addition of organometallics to carbonyl compounds. The problem with this reaction is that no-one really knows precisely what happens during the addition reaction. We know what the organic products are because we can isolate them and look at them using NMR and other spectroscopic techniques. But what happens to the metal atoms during the reaction?

You will have noticed that we always write the addition reaction with the metal atom just falling off the organometallic as it reacts, and then appearing near to the anionic oxygen atom of the product. In other words, we have not been specific about what the metal atom is actually doing during the addition; in fact, we have been deliberately vague so as not to imply anything that may not be true. But there is one thing that is certain about this process, and before we discuss it we need to remind you of something we talked about in Chapter 6: the effect of acid on the addition of nucleophiles to carbonyl groups. We said that acid tends to catalyse addition reactions by protonating the carbonyl group, making it positively charged and therefore more electrophilic.

Now, of course, in our organometallic addition reactions we have no acid (H⁺) present, because that would destroy the organometallic reagent. But we do have Lewis-acidic metal atoms—Li or Mg—and these can play exactly the same role. They can coordinate to the carbonyl’s oxygen atom, giving the carbonyl group positive charge and therefore making it more electrophilic. In one possible version of the mechanism, a four-centred mechanism allows coordination of the magnesium to the oxygen while the nucleophilic carbon atom attacks the carbonyl group. The product ends up with a (covalent) Mg–O bond, but this is just another way of writing RO⁻MgBr⁺.

The four-centred mechanism is quite hard to visualize just with curly arrows: what they are saying is that the O–Mg interaction is forming at the same time as the new C–C bond, and that simultaneously the old C–Mg bond and C=O π bond are breaking. A neat way of representing all of this is to draw what we might see if we took a snapshot of the reaction halfway through, using dotted lines to represent the partially formed or partially broken bonds. It would look something like this, and such a snapshot is known as the transition state for the reaction.

An alternative possibility is that two molecules of the Grignard reagent are involved, and that the transition state is a six-membered ring. We are telling you all this not because we want to confuse you but because we want to be honest: there is genuine uncertainty about the mechanism, and this arises because, while it is easy to determine the products of a reaction using spectroscopy, it is much harder to determine mechanisms.

But, for one type of Grignard reagent, it is certain that the addition proceeds through a six-membered ring. Here is a reaction between an allylic Grignard reagent and a ketone. The product is a tertiary alcohol, but perhaps not the tertiary alcohol you would expect. The Grignard reagent appears to
have attached itself via the wrong carbon atom. We can explain this by a six-membered transition state, but one involving only one molecule of Grignard reagent.

Allylic Grignard reagents are unusual for more than one reason, and it turns out that they are, in fact, quite hard to make in good yield from allyl halides. The problem is that the allyl halide is highly reactive towards the Grignard reagent as it forms, and a major by-product tends to be a dimer. The way round this problem is to make the Grignard reagent actually in the presence of the carbonyl compound. This method works in a number of cases, not just with allylic Grignards, and is often called the Barbier method.

For example, it is a straightforward matter to make these three alcohols, provided the allylic halide, aldehyde, and magnesium are all mixed together in one flask. The Grignard reagent forms, and immediately reacts with the aldehyde, before it has a chance to dimerize. In the second example, notice again that the allylic Grignard reagent must have reacted through a six-membered transition state because the allyl system has 'turned around' in the product.

The last reaction above leads us nicely into the next chapter where we will look at an alternative way for such unsaturated aldehydes to react—by conjugate addition.

Problems

1. Propose mechanisms for the first four reactions in the chapter.
2. When this reaction is carried out with allyl bromide labelled as shown with $^{13}$C, the label is found equally distributed between the ends of the allyl system in the product. Explain how this is possible. How would you detect the $^{13}$C distribution in the product?

3. What products would be formed in these reactions?

4. Suggest alternative routes to fenarimol—that is, different routes from the one shown in the chapter.

5. The synthesis of the gastric antisecretory drug rioprostil requires this alcohol. (a) Suggest possible syntheses starting from ketones and organometallics and (b) suggest possible syntheses of the ketones in part (a) from aldehydes and organometallics (don’t forget about CrO₃ oxidation!).

6. Suggest two syntheses of the bee pheromone heptan-2-one.

7. How could you prepare these compounds using ortholithiation procedures?

8. Why is it possible to make the lithium derivative A by Br/Li exchange, but not the lithium derivative B?

9. Comment on the selectivity (that is, say what else might have happened and why it didn’t) shown in this Grignard addition reaction used in the manufacture of an antihistamine drug.

10. The antispasmodic drug biperidin is made by the Grignard addition reaction shown here. What is the structure of the drug? Do not be put off by the apparent complexity of the compounds—the chemistry is the same as that you have seen in this chapter. How would you suggest that the drug procyclidine should be made?

11. Though heterocyclic compounds, such as the nitrogen ring system in this question, are introduced rather later in this book, use your knowledge of Grignard chemistry to draw a mechanism for what happens here. It is important that you prove to yourself that you can draw mechanisms for reactions on compounds that you have never met before.
12. What product would be formed in this reaction between a chloro compound and a seven-membered ring ketone?
Conjugation changes the reactivity of carbonyl groups

To start this chapter, here are four reactions of the same ketone. For each product, the principal absorptions in the IR spectrum are listed. The pair of reactions on the left should come as no surprise to you: nucleophilic addition of cyanide or a Grignard reagent to the ketone produces a product with no C=O peak near 1700 cm\(^{-1}\), but instead an O–H peak at 3600 cm\(^{-1}\). The 2250 cm\(^{-1}\) peak is C≡N; C=C is at 1650 cm\(^{-1}\).

But what about the reactions on the right? Both products A and B have kept their carbonyl group (IR peak at 1710 cm\(^{-1}\)) but have lost the C=C. Yet A, at least, is definitely an addition product because it contains a C≡N peak at 2200 cm\(^{-1}\).

Well, the identities of A and B are revealed here: they are the products of addition, not to the carbonyl group, but to the C=C bond. This type of reaction is called conjugate addition, and is what this chapter is all about. The chapter will also explain how such small differences in reaction conditions (temperature, or the presence of CuCl) manage to change the outcome completely.

direct addition to the C=O group
Conjugate addition to the C=C double bond follows a similar course to direct addition to the C=O group, and the mechanisms for both are shown here. Both mechanisms have two steps: addition, followed by protonation. Conjugate additions only occur to C=C double bonds next to C=O groups. They don’t occur to C=C bonds that aren’t immediately adjacent to C=O (see the box on p. 000 for an example).

Compounds with double bonds adjacent to a C=O group are known as α,β-unsaturated carbonyl compounds. Many α,β-unsaturated carbonyl compounds have trivial names, and some are shown here. Some classes of α,β-unsaturated carbonyl compounds also have names such as ‘enone’ or ‘enal’, made up of ‘ene’ (for the double bond) + ‘one’ (for ketone) or ‘ene’ + ‘al’ (for aldehyde).

A range of nucleophiles will undergo conjugate additions with α,β-unsaturated carbonyl compounds, and six examples are shown below. Note the range of nucleophiles, and also the range of carbonyl compounds: esters, aldehydes, acids, and ketones.
The reason that $\alpha,\beta$-unsaturated carbonyl compounds react differently is conjugation, the phenomenon we discussed in Chapter 7. There we introduced you to the idea that bringing two $\pi$ systems (two C=C bonds, for example, or a C=C bond and a C=O bond) close together leads to a stabilizing interaction. It also leads to modified reactivity, because the $\pi$ bonds no longer react as independent functional groups but as a single, conjugated system.

**Termite self-defence and the reactivity of alkenes**

Soldier termites of the species *Schedorhinotermes lamanianus* defend their nests by producing this compound, which is very effective at taking part in conjugate addition reactions with thiols (RSH). This makes it highly toxic, since many important biochemicals carry SH groups. The worker termites of the same species—who build the nests—need to be able to avoid being caught in the crossfire, so they are equipped with an enzyme that allows them to reduce compound 1 to compound 2. This still has a double bond, but the double bond is completely unreactive towards nucleophiles because it is not conjugated with a carbonyl group. The workers escape unharmed.

**Alkenes conjugated with carbonyl groups are polarized**

You haven’t met many reactions of alkenes yet; detailed discussion will have to wait till Chapter 20. But we did indicate in Chapter 5 that they react with electrophiles. Here is the example from p. 000: in the addition of HBr to isobutene the alkene acts as a nucleophile and H–Br as the electrophile.

$$\text{Me} = \text{CH}_2 \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me}$$

This is quite different to the reactivity of a C=C double bond conjugated with a carbonyl group, which, as you have just seen, reacts with nucleophiles such as cyanide, amines, and alcohols. The conjugated system is different from the sum of the isolated parts, with the C=O group profoundly affecting the reactivity of the C=C double bond. To show why, we can use curly arrows to indicate delocalization of the $\pi$ electrons over the four atoms in the conjugated system. Both representations are extremes, and the true structure lies somewhere in between, but the polarized structure indicates why the conjugated C=C bond is electrophilic.

**Polarization is detectable spectroscopically**

IR spectroscopy provides us with evidence for polarization in C=C bonds conjugated to C=O bonds. An unconjugated ketone C=O absorbs at 1715 cm$^{-1}$ while an unconjugated alkene C=C absorbs...
(usually rather weakly) at about 1650 cm\(^{-1}\). Bringing these two groups into conjugation in an \(\alpha,\beta\)-unsaturated carbonyl compound leads to two peaks at 1675 and 1615 cm\(^{-1}\), respectively, both quite strong. The lowering of the frequency of both peaks is consistent with a weakening of both \(\pi\) bonds (notice that the polarized structure has only single bonds where the C=O and C=C double bonds were). The increase in the \textit{intensity} of the C=C absorption is consistent with polarization brought about by conjugation with C=O: a conjugated C=C bond has a significantly larger dipole moment than its unconjugated cousins.

The polarization of the C=C bond is also evident in the \(^{13}\)C NMR spectrum, with the signal for the sp\(^2\) carbon atom furthest from the carbonyl group moving downfield relative to an unconjugated alkene to about 140 p.p.m., and the signal for the other double bond carbon atom staying at about 120 p.p.m.

![Diagram of molecular orbitals control conjugate additions](image)

**Molecular orbitals control conjugate additions**

We have spectroscopic evidence that a conjugated C=C bond is polarized, and we can explain this with curly arrows, but the actual bond-forming step must involve movement of electrons from the HOMO of the nucleophile to the LUMO of the unsaturated carbonyl compound. The example in the margin has methoxide (MeO\(^{-}\)) as the nucleophile.

But what does this LUMO look like? It will certainly be more complicated than the \(\pi^*\) LUMO of a simple carbonyl group. The nearest thing you have met so far (in Chapter 7) are the orbitals of butadiene (C=C conjugated with C=C), which we can compare with the \(\alpha,\beta\)-unsaturated aldehyde acrolein (C=C conjugated with C=O). The orbitals in the \(\pi\) systems of butadiene and acrolein are shown here. They are different because acrolein’s orbitals are perturbed (distorted) by the oxygen atom (Chapter 4). You need not be concerned with exactly how the sizes of the orbitals are worked out, but for the moment just concentrate on the shape of the LUMO, the orbital that will accept electrons when a nucleophile attacks.

In acrolein, the HOMO is in fact not the highest filled \(\pi\) orbital you see here, but the lone pairs on oxygen. This is not important here, though, because we are only considering acrolein as an electrophile, so we are only interested in its LUMO.
that gives rise to the new bond. The second largest coefficient is on the C=O carbon atom, so it’s not surprising that some nucleophiles attack here as well—remember the example right at the beginning of the chapter where you saw cyanide attacking either the double bond or the carbonyl group depending on the conditions of the reaction. We shall next look at some conjugate additions with alcohols and amines as nucleophiles, before reconsidering the question of where the nucleophile attacks.

Ammonia and amines undergo conjugate addition

Amines are good nucleophiles for conjugate addition reactions, and give products that we can term β-amino carbonyl compounds (the new amino group is β to the carbonyl group). Dimethylamine is a gas at room temperature, and this reaction has to be carried out in a sealed system to give the ketone product.

This is the first conjugate addition mechanism we have shown you that involves a neutral nucleophile: as the nitrogen adds it becomes positively charged and therefore needs to lose a proton. We can use this proton to protonate the negatively charged part of the molecule as you have seen happening before. This proton-transfer step can alternatively be carried out by a base: in this addition of butylamine to an α,β-unsaturated ester (ethyl acrylate), the added base (EtO⁻) deprotonates the nitrogen atom once the amine has added. Only a catalytic amount is needed, because it is regenerated in the step that follows.

Ammonia itself, the simplest amine, is very volatile (it is a gas at room temperature, but a very water-soluble one, and bottles of ‘ammonia’ are actually a concentrated aqueous solution of ammonia), and the high temperatures required for conjugate addition to this unsaturated carboxylic acid can only be achieved in a sealed reaction vessel.
Amines are bases as well as nucleophiles, and in this reaction the first step must be deprotonation of the carboxylic acid: it’s the ammonium carboxylate that undergoes the addition reaction. You would not expect a negatively charged carboxylate to be a very good electrophile, and this may well be why ammonia needs 150 °C to react.

The β-amino carbonyl product of conjugate addition of an amine is still an amine and, provided it has a primary or secondary amino group, it can do a second conjugate addition. For example, methylamine adds successively to two molecules of this unsaturated ester.

Two successive conjugate additions can even happen in the same molecule. In the next example, hydroxylamine is the nucleophile. Hydroxylamine is both an amine and an alcohol, but it always reacts at nitrogen because nitrogen (being less electronegative than oxygen) has a higher-energy (more reactive) lone pair. Here it reacts with a cyclic dienone to produce a bicyclic ketone, which we have also drawn in a perspective view to give a better idea of its shape.

The reaction sequence consists of two conjugate addition reactions. The first is intermolecular, and gives the intermediate enone. The second conjugate addition is intramolecular, and turns the molecule into a bicyclic structure. Again, the most important steps are the C=N bond-forming reactions, but there are also several proton transfers that have to occur. We have shown a base ‘B’ carrying out these proton transfers: this might be a molecule of hydroxylamine, or it might be a molecule of the solvent, methanol. These details do not matter.
Conjugate addition of alcohols can be catalysed by acid or base

Alcohols undergo conjugate addition only very slowly in the absence of a catalyst: they are not such good nucleophiles as amines for the very reason we have just mentioned in connection with the reactivity of hydroxylamine—oxygen is more electronegative than nitrogen, and so its lone pairs are of lower energy and are therefore less reactive. Alkoxide anions are, however, much more nucleophilic. You saw methoxide attacking the orbitals of acrolein above: the reaction in the margin goes at less than 5 °C.

The alkoxide doesn’t have to be made first, though, because alcohols dissolved in basic solution are at least partly deprotonated to give alkoxide anions. How much alkoxide is present depends on the pH of the solution and therefore the pKₐ of the base (Chapter 8), but even a tiny amount is acceptable because once this has added it will be replaced by more alkoxide in acid–base equilibrium with the alcohol. In this example, allyl alcohol adds to pent-2-enal, catalysed by sodium hydroxide in the presence of a buffer.

Only a catalytic amount of base is required as the deprotonation of ROH (which can be water or allyl alcohol) in the last step regenerates more alkoxide or hydroxide. It does not matter that sodium hydroxide (pKₐH 15.7) is not basic enough to deprotonate an alcohol (pKₐ 16–17) completely, since only a small concentration of the reactive alkoxide is necessary for the reaction to proceed.

We can also make rings using alkoxide nucleophiles, and in this example the phenol (hydroxybenzene) is deprotonated by the sodium methoxide base to give a phenoxide anion. Intramolecular attack on the conjugated ketone gives the cyclic product in excellent yield. In this case, the methoxide (pKₐH about 16) will deprotonate the phenol (pKₐ about 10) completely, and competitive attack by MeO⁻ acting as a nucleophile is not a problem as intramolecular reactions are usually faster than their intermolecular equivalents.
Acid catalysts promote conjugate addition of alcohols to $\alpha,\beta$-unsaturated carbonyl compounds by protonating the carbonyl group and making the conjugated system more electrophilic. Methanol adds to this ketone exceptionally well, for example, in the presence of an acid catalyst known as ‘Dowex 50’. This is an acidic resin—just about as acidic as sulfuric acid in fact, but completely insoluble, and therefore very easy to remove from the product at the end of the reaction by filtration.

Once the methanol has added to the protonated enone, all that remains is to reorganize the protons in the molecule to give the product. This takes a few steps, but don’t be put off by their complexity—as we’ve said before, the important step is the first one—the conjugate addition.

**Conjugate addition or direct addition to the carbonyl group?**

We have shown you several examples of conjugate additions using various nucleophiles and $\alpha,\beta$-unsaturated carbonyl compounds, but we haven’t yet addressed one important question. When do nucleophiles do conjugate addition (also called ‘1,4-addition’) and when do they add directly to the carbonyl group (‘1,2-addition’)? Several factors are involved—they are summarized here, and we will spend the next section of this chapter discussing them in turn.

**Reaction conditions**

The very first conjugate addition reaction in this chapter depended on the conditions of the reaction. Treating an enone with cyanide and an acid catalyst at low temperature gives a cyanohydrin by direct attack at C=O, while heating the reaction mixture leads to conjugate addition. What is going on?
We’ll consider the low-temperature reaction first. As you know from Chapter 6, it is quite normal for cyanide to react with a ketone under these conditions to form a cyanohydrin. Direct addition to the carbonyl group turns out to be faster than conjugate addition, so we end up with the cyanohydrin.

Now, you also know from Chapter 6 that cyanohydrin formation is reversible. Even if the equilibrium for cyanohydrin formation lies well over to the side of the products, at equilibrium there will still be a small amount of starting enone remaining. Most of the time, this enone will react to form more cyanohydrin and, as it does, some cyanohydrin will decompose back to enone plus cyanide—such is the nature of a dynamic equilibrium. But every now and then—at a much slower rate—the starting enone will undergo a conjugate addition with the cyanide. Now we have a different situation: conjugate addition is essentially an irreversible reaction, so once a molecule of enone has been converted to conjugate addition product, its fate is sealed: it cannot go back to enone again. Very slowly, therefore, the amount of conjugate addition product in the mixture will build up. In order for the enone–cyanohydrin equilibrium to be maintained, any enone that is converted to conjugate addition product will have to be replaced by reversion of cyanohydrin to enone plus cyanide. Even at room temperature, we can therefore expect the cyanohydrin to be converted bit by bit to conjugate addition product. This may take a very long time, but reaction rates are faster at higher temperatures, so at 80 °C this process does not take long at all and, after a few hours, the cyanohydrin has all been converted to conjugate addition product.

The contrast between the two products is this: cyanohydrin is formed faster than the conjugate addition product, but the conjugate addition product is the more stable compound.

Typically, kinetic control involves lower temperatures and shorter reaction times, which ensures that only the fastest reaction has the chance to occur. And, typically, thermodynamic control involves higher temperatures and long reaction times to ensure that even the slower reactions have a chance to occur, and all the material is converted to the most stable compound.

**Kinetic and thermodynamic control**

- The product that forms faster is called the **kinetic product**
- The product that is the more stable is called the **thermodynamic product**

Similarly,
- Conditions that give rise to the kinetic product are called **kinetic control**
- Conditions that give rise to the thermodynamic product are called **thermodynamic control**

Why is direct addition faster than conjugate addition? Well, although the carbon atom β to the C=O group carries some positive charge, the carbon atom of the carbonyl group carries more, and so electrostatic attraction for the charged nucleophiles will encourage it to attack the carbonyl group directly rather than undergo conjugate addition.

[Diagram showing the reaction mechanisms]
And why is the conjugate addition product the more stable? In the conjugate addition product, we gain a C–C σ bond, losing a C=O π bond, but keeping the C=O π bond. With direct addition, we still gain a C–C bond, but we lose the C=O π bond and keep the C=C π bond. C=O π bonds are stronger than C=C π bonds, so the conjugate addition product is the more stable.

We will return to kinetic and thermodynamic control in Chapter 13, where we will analyse the rates and energies involved a little more rigorously, but for now here is an example where conjugate addition is ensured by thermodynamic control. Note the temperature!

Structural factors

Not all additions to carbonyl groups are reversible: additions of organometallics, for example, are certainly not. In such cases, the site of nucleophilic attack is determined simply by reactivity: the more reactive the carbonyl group, the more direct addition to C=O will result. The most reactive carbonyl groups, as you will see in Chapter 12, are those that are not conjugated with O or N (as they are in esters and amides), and particularly reactive are acyl chlorides and aldehydes. In general, the proportion of direct addition to the carbonyl group follows the reactivity sequence in the margin.

Compare the way butyllithium adds to this α,β-unsaturated aldehyde and α,β-unsaturated amide. Both additions are irreversible, and BuLi attacks the reactive carbonyl group of the aldehyde, but prefers conjugate addition to the less reactive amide. Similarly, ammonia reacts with this acyl chloride to give an amide product that derives (for details see Chapter 12) from direct addition to the carbonyl group, while with the ester it undergoes conjugate addition to give an amine.

Sodium borohydride is a nucleophile that you have seen reducing simple aldehydes and ketones to alcohols, and it usually reacts with α,β-unsaturated aldehydes in a similar way, giving alcohols by direct addition to the carbonyl group.

Quite common with ketones, though, is the outcome on the right. The borohydride has reduced
not only the carbonyl group but the double bond as well. In fact, it’s the double bond that’s reduced first in a conjugate addition, followed by addition to the carbonyl group.

For esters and other less reactive carbonyl compounds conjugate addition is the only reaction that occurs.

Steric hindrance also has a role to play: the more substituents there are at the β carbon, the less likely a nucleophile is to attack there. Nonetheless, there are plenty of examples where nucleophiles undergo conjugate addition even to highly substituted carbon atoms.

The nature of the nucleophile: hard and soft

Among the best nucleophiles of all at doing conjugate addition are thiols, the sulfur analogues of alcohols. In this example, the nucleophile is thiophenol (phenol with the O replaced by S). Remarkably, no acid or base catalyst is needed (as it was with the alcohol additions), and the product is obtained in 94% yield under quite mild reaction conditions.

Why are thiols such good nucleophiles for conjugate additions? Well, to explain this, and why they are much less good at direct addition to the C=O group, we need to remind you of some ideas we introduced in Chapter 5. There we said that the attraction between nucleophiles and electrophiles is governed by two related interactions—electrostatic attraction between positive and negative charges and orbital overlap between the HOMO of the nucleophile and the LUMO of the electrophile. Successful reactions usually result from a combination of both, but sometimes reactivity can be dominated by one or the other. The dominant factor, be it electrostatic or orbital control, depends on the nucleophile and electrophile involved. Nucleophiles containing small, electronegative atoms (such as O or Cl) tend to react under predominantly electrostatic control, while nucleophiles containing larger atoms (including the sulfur of thiols, but also P, I, and Se) are predominantly subject to control by orbital overlap. The terms ‘hard’ and ‘soft’ have been coined to describe these two types of reagents. Hard nucleophiles are typically from the early rows of the periodic table and have higher charge density, while soft nucleophiles are from the later rows of the periodic table—they are either uncharged or have larger atoms with higher-energy, more diffuse orbitals.

Table 10.1 divides some nucleophiles into the two categories (plus some that lie in between)—but don’t try to learn it! Rather, convince yourself that the properties of each one justify its location in the table. Most of these nucleophiles you have not yet seen in action, and the most important ones at this stage are indicated in bold type.
Not only can nucleophiles be classified as hard or soft, but electrophiles can too. For example, $\text{H}^+$ is a very hard electrophile because it is small and charged, while $\text{Br}_2$ is a soft electrophile: its orbitals are diffuse and it is uncharged. You saw $\text{Br}_2$ reacting with an alkene earlier in the chapter, and we explained in Chapter 5 that this reaction happens solely because of orbital interactions: no charges are involved. The carbon atom of a carbonyl group is also a hard electrophile because it carries a partial positive charge due to polarization of the C=O bond. What is important to us is that, in general, hard nucleophiles prefer to react with hard electrophiles, and soft nucleophiles with soft electrophiles. So, for example, water (a hard nucleophile) reacts with aldehydes (hard electrophiles) to form hydrates in a reaction largely controlled by electrostatic attraction. On the other hand, water does not react with bromine (a soft electrophile). Yet bromine reacts with alkenes while water does not. Now this is only a very general principle, and you will find plenty of examples where hard reacts with soft and soft with hard. Nonetheless it is a useful concept, which we shall come back to later in the book.

**Hard/soft reactivity**

- Reactions of hard species are dominated by charges and electrostatic effects
- Reactions of soft species are dominated by orbital effects
- Hard nucleophiles tend to react well with hard electrophiles
- Soft nucleophiles tend to react well with soft electrophiles

What has all this to do with the conjugate addition of thiols? Well, an $\alpha,\beta$-unsaturated carbonyl compound is unusual in that it has two electrophilic sites, one of which is hard and one of which is soft. The carbonyl group has a high partial charge on the carbonyl carbon and will tend to react with hard nucleophiles, such as organolithium and Grignard reagents, that have a high partial charge on the nucleophilic carbon atom. Conversely, the $\beta$ carbon of the $\alpha,\beta$-unsaturated carbonyl system does not have a high partial positive charge but is the site of the largest coefficient in the LUMO. This makes the $\beta$ carbon a soft electrophile and likely to react well with soft nucleophiles such as thiols.

**Hard/soft—direct/conjugate addition**

- Hard nucleophiles tend to react at the carbonyl carbon (hard) of an enone
- Soft nucleophiles tend to react at the $\beta$-carbon (soft) of an enone and lead to conjugate addition

### Anticancer drugs that work by conjugate addition of thiols

Drugs to combat cancer act on a range of biochemical pathways, but most commonly on processes that cancerous cells need to use to proliferate rapidly. One class attacks DNA polymerase, an enzyme needed to make the copy of DNA that has to be provided for each new cell. Helenalin and vernolepin are two such drugs, and if you look closely at their structure you should be able to spot two $\alpha,\beta$-unsaturated carbonyl groups in each. Biochemistry is just chemistry in very small flasks called cells, and the reaction between DNA polymerase and these drugs is simply a conjugate addition reaction between a thiol (the SH group of one of the enzyme’s cysteine residues) and the unsaturated carbonyl groups. The reaction is irreversible, and shuts down completely the function of the enzyme.
Copper(I) salts have a remarkable effect on organometallic reagents

Grignard reagents add directly to the carbonyl group of α,β-unsaturated aldehydes and ketones to give allylic alcohols: you have seen several examples of this, and you can now explain it by saying that the hard Grignard reagent prefers to attack the harder C=O rather than the softer C=C electrophilic centre. Here is a further example—the addition of MeMgI to a cyclic ketone to give an allylic alcohol, plus, as it happens, some of a diene that arises from this alcohol by loss of water (dehydration). Below this example is the same reaction to which a very small amount (just 0.01 equivalents, that is, 1%) of copper(I) chloride has been added. The effect of the copper is dramatic: it makes the Grignard reagent undergo conjugate addition, with only a trace of the diene.

Organocopper reagents undergo conjugate addition

The copper works by transmetallating the Grignard reagent to give an organocopper reagent. Organocoppers are softer than Grignard reagents, and add in a conjugate fashion to the softer C=C double bond. Once the organocopper has added, the copper salt is available to transmetallate some more Grignard, and only a catalytic amount is required.

Organocoppers are softer than Grignard reagents because copper is less electropositive than magnesium, so the C–Cu bond is less polarized than the C–Mg bond, giving the carbon atom less of a partial negative charge. Electronegativities: Mg, 1.3; Cu, 1.9.

The organocopper is shown here as ‘Me–Cu’ because its precise structure is not known. But there are other organocopper reagents that also undergo conjugate addition and that are much better understood. The simplest result from the reaction of two equivalents of organolithium with one equivalent of a copper (I) salt such as CuBr in ether or THF solvent at low temperature. The lithium cuprates (R₂CuLi) that are formed are not stable and must be used immediately.

As with the organolithiums that we introduced in Chapter 9, the exact structure of these reagents is more complex than we imply here: they are probably tetramers (four molecules of R₂CuLi bound together), but for simplicity we will draw them as monomers.
The addition of lithium cuprates to \(\alpha,\beta\)-unsaturated ketones turns out to be much better if trimethylsilyl chloride is added to the reaction—we will explain what this does shortly, but for the moment here are two examples of lithium cuprate additions.

The silicon works by reacting with the negatively charged intermediate in the conjugate addition reaction to give a product that decomposes to the carbonyl compound when water is added at the end of the reaction. Here is a possible mechanism for a reaction between \(\text{Bu}_2\text{CuLi}\) and an \(\alpha,\beta\)-unsaturated ketone in the presence of \(\text{Me}_3\text{SiCl}\). The first step is familiar to you, but the second is a new reaction. Even so, following what we said in Chapter 5, it should not surprise you: the oxygen is clearly the nucleophile and the silicon the electrophile, and a new bond forms from O to Si as indicated by the arrow. The silicon-containing product is called a silyl enol ether, and we will come back to these compounds and their chemistry in more detail in later chapters.

**Conclusion**

We end with a summary of the factors controlling the two modes of addition to \(\alpha,\beta\)-unsaturated carbonyl compounds, and by noting that conjugate addition will be back again—in Chapters 23 (where we consider electrophilic alkenes conjugated with groups other than C=O) and 29 (where the nucleophiles will be of a different class known as enolates).

Problems

1. Draw mechanisms for this reaction and explain why this particular product is formed.

2. Which of the two routes shown here would actually lead to the product? Why?

3. Suggest reasons for the different outcomes of the following reactions (your answer must, of course, include a mechanism for each reaction).

4. Addition of dimethylamine to the unsaturated ester A could give either product B or C. Draw mechanisms for both reactions and show how you would distinguish them spectroscopically.

5. Suggest mechanisms for the following reactions.

6. Predict the product of these reactions.

7. Two routes are proposed for the preparation of this amino alcohol. Which do you think is more likely to succeed and why?

8. How would you prepare these compounds by conjugate addition?

9. How might this compound be made using a conjugate addition as one of the steps? You might find it helpful to consider the preparation of tertiary alcohols as described in Chapter 9 and also to refer back to Problem 1 in this chapter.

10. When we discussed reduction of cyclopentenone to cyclopentanol, we suggested that conjugate addition of borohydride must occur before direct addition of borohydride; in other words, this scheme must be followed.

What is the alternative scheme? Why is the scheme shown above definitely correct?
11. Suggest a mechanism for this reaction. Why does conjugate addition occur rather than direct addition?

Why is the product shown as a cation? If it is indeed a salt, what is the anion?

12. How, by choice of reagent, would you make this reaction give the direct addition product (route A)? How would you make it give the conjugate addition product (route B)?
The differences between carbon and proton NMR

We used $^{13}$C NMR in Chapter 3 as part of a three-pronged attack on the problem of determining molecular structure. Important though these three prongs are, we were forced to confess at the end of Chapter 3 that we had delayed the most important technique of all—proton ($^1$H) NMR—until a later chapter because it is more complicated than $^{13}$C NMR. This is that delayed chapter and we must now tackle those complications. We hope you will see $^1$H NMR for the beautiful and powerful technique that it surely is. The difficulties are worth mastering for this is the chemist’s primary weapon in the battle to solve structures.

Proton NMR differs from $^{13}$C NMR in a number of ways.

- $^1$H is the major isotope of hydrogen (99.985% natural abundance), while $^{13}$C is only a minor isotope (1.1%)
- $^1$H NMR is quantitative: the area under the peak tells us the number of hydrogen nuclei, while $^{13}$C NMR may give strong or weak peaks from the same number of $^{13}$C nuclei
- Protons interact magnetically (‘couple’) to reveal the connectivity of the structure, while $^{13}$C is too rare for coupling between $^{13}$C nuclei to be seen
- $^1$H NMR shifts give a more reliable indication of the local chemistry than that given by $^{13}$C spectra

We shall examine each of these points in detail and build up a full understanding of proton NMR spectra. The other spectra remain important, of course.

Proton NMR spectra are recorded in the same way as $^{13}$C NMR spectra: radio waves are used to study the energy level differences of nuclei, but this time they are $^1$H and not $^{13}$C nuclei. Hydrogen nuclei have a nuclear spin...
of a half and so have two energy levels: they can be aligned either with or against the applied magnetic field.

The spectra look much the same: the scale runs from right to left and the zero point is given by the same reference compound though it is the proton resonance of Me₄Si rather than the carbon resonance that defines the zero point. You will notice at once that the scale is much smaller, ranging over only about 10 p.p.m. instead of the 200 p.p.m. needed for carbon. This is because the variation in the chemical shift is a measure of the shielding of the nucleus by the electrons around it. There is inevitably less change possible in the distribution of two electrons around a hydrogen nucleus than in that of the eight valence electrons around a carbon nucleus. Here is a simple ¹H NMR spectrum.

Integration tells us the number of hydrogen atoms in each peak

The chemical shift of the twelve hydrogen atoms of the four identical methyl groups in Me₄Si is defined as zero. The methyl group in the acid is next to the carbonyl group and so slightly deshielded at about δ 2.0 p.p.m. and the acidic proton itself is very deshielded at δ 11.2 p.p.m. The same factor that makes this proton acidic—the O–H bond is polarized towards oxygen—also makes it resonate at low field. So far things are much the same as in carbon NMR. Now for a difference. Notice that the ratio of the peak heights in this spectrum was about 3:1 and that is also the ratio of the number of protons. In fact, it’s not the peak height but the area under the peaks that is exactly proportional to the number of protons. Proton spectra are normally integrated, that is, the area under the peaks is computed and recorded as a line with steps corresponding to the area, like this.

Simply measuring the height of the steps with a ruler gives you the ratio of the numbers of protons represented by each peak. Knowing the atomic composition from the mass spectrum, we also know the distribution of protons of various kinds. Here the heights are 0.75 and 2.25 cm, a ratio of about 1:3. The compound is C₂H₄O₂ so, since there are 4 H atoms altogether, the peaks must contain 1 × H and 3 × H, respectively.

In the spectrum of 1,4-dimethoxybenzene, there are just two signals in the ratio of 3:2. This time the compound is C₈H₁₀O₂ so the true ratio must be 6:4. Assigning the spectrum requires the same attention to symmetry as in the case of ¹³C spectra.
In this next example it is easy to assign the spectrum simply by measuring the steps in the integral. There are two identical methyl groups (CMe₂) having 6 Hs, one methyl group by itself having 3 Hs, the OH proton (1 H), the CH₂ group next to the OH (2 Hs), and finally the CH₂CH₂ group between the oxygen atoms in the ring (4 Hs).

Proton NMR spectra are generally recorded in solution in deuterochloroform (CDCl₃)—that is, chloroform with the ¹H replaced by ²H. The proportionality of the size of the peak to the number of protons tells you why: if you ran a spectrum in CHCl₃, you would see a vast peak for all the solvent Hs because there would be much more solvent than the compound you wanted to look at. Using CDCl₃ cuts out all extraneous protons.

**Regions of the proton NMR spectrum**

The integration gives useful—indeed essential—information, but it is much more important to understand the reasons for the exact chemical shift of the different types of proton. In the last example you can see one marked similarity to carbon spectra: protons on saturated carbon atoms next to oxygen are shifted downfield to larger δ values (here 3.3 and 3.9 p.p.m.). The other regions of the proton NMR spectrum are also quite similar in general outline to those of ¹³C spectra. Here they are.
These regions hold for protons attached to C; protons attached to O or N can come almost anywhere on the spectrum. Even for C–H signals, the regions are approximate and overlap quite a lot. You should use the chart as a basic guide, but you will need a more detailed understanding of proton chemical shifts than you did for $^{13}$C chemical shifts. To achieve this understanding, we now need to examine each class of proton in more detail and examine the reasons for particular shifts. It is important that you grasp these reasons. An alternative is to learn all the chemical shifts off by heart (not recommended).

Protons on saturated carbon atoms

Chemical shifts are related to the electronegativity of substituents

We shall start with protons on saturated carbon atoms. If you study Table 11.1 you will see that the protons in a methyl group are shifted more and more as the atom attached to them gets more electronegative.

When we are dealing with simple atoms as substituents, these effects are straightforward and more or less additive. If we go on adding electronegative chlorine atoms to a carbon atom, electron density is progressively removed from it and the carbon nucleus and the hydrogen atoms attached to it are progressively deshielded.

Proton chemical shifts tell us about chemistry

The truth is that shifts and electronegativity are not perfectly correlated. The key property is indeed electron withdrawal but it is the electron-withdrawing power of the whole substituent in comparison with the carbon and hydrogen atoms in the CH skeleton that matters. Methyl groups joined to the same element, say, nitrogen, may have very different shifts if the substituent is an amino group ($\text{CH}_3\text{–NH}_2$ has $\delta_H$ for the CH group = 2.41 p.p.m.) or a nitro group ($\text{CH}_3\text{–NO}_2$ has $\delta_H$ 4.33 p.p.m.). A nitro group is much more electron-withdrawing than an amino group.

What we need is a quick guide rather than some detailed correlations, and the simplest is this: all functional groups except very electron-withdrawing ones shift methyl groups from 1 p.p.m. (where you find them if they are not attached to a functional group) downfield to about 2 p.p.m. Very electron-withdrawing groups shift methyl groups to about 3 p.p.m.
Rather than trying to fit these data to some atomic property, even such a useful one as electronegativity, we should rather see these shifts as a useful measure of the electron-withdrawing power of the group in question. The NMR spectra are telling us about the chemistry. Among the largest shifts possible for a methyl group is that caused by the nitro group, 3.43 p.p.m., at least twice the size of the shift for a carbonyl group. This gives us our first hint of some important chemistry: one nitro group is worth two carbonyl groups when you need electron withdrawal. You have already seen that electron withdrawal and acidity are related (Chapter 8) and in later chapters you will see that we can correlate the anion-stabilizing power of groups like carbonyl, nitro, and sulfone with proton NMR.

Methyl groups give us information about the structure of molecules

It sounds rather unlikely that the humble methyl group could tell us much that is important about molecular structure—but just you wait. We shall look at four simple compounds and their NMR spectra—just the methyl groups, that is. The first two are the acid chlorides on the right.

The first compound shows just one methyl signal containing 9 Hs at δ_H 1.10 p.p.m.. This tells us two things. All the protons in each methyl group are the same; and all three methyl groups in the tertiary butyl (t-butyl, or Me_3C–) group are the same. This is because rotation about C–C single bonds, both about the CH_3–C bond and about the (CH_3)_3C–C bond, is fast. Though at any one instant the hydrogen atoms in one methyl group, or the methyl groups in the t-butyl group, may differ, on average they are the same. The time-averaging process is fast rotation about a σ bond. The second compound shows two 3H signals, one at 1.99 and one at 2.17 p.p.m.. Now rotation is slow—indeed the C=C double bond does not rotate at all and so the two methyl groups are different. One is on the same side of the alkene as (or ‘cis to’) the –COCl group while the other is on the opposite side (or ‘trans’).

The second pair of compounds contain the CHO group. One is a simple aldehyde, the other an amide of formic acid: it is DMF, dimethylformamide. The first has two sorts of methyl group: a 3H signal at δ_H 1.81 p.p.m. for the SMe group and a 6H signal for the CMe_2 group. The two methyl groups in the 6H signal are the same, again because of fast rotation about a C–C σ bond.

The second compound also has two methyl signals, at 2.89 and 2.98 p.p.m., each 3H, and these are the two methyl groups on nitrogen. Restricted rotation about the N–CO bond must be making the two Me groups different. You will remember from Chapter 7 (p. 000) that the N–CO amide bond has considerable double bond character because of conjugation: the lone pair electrons on nitrogen are delocalized into the carbonyl group.
Chemical shifts of \(\text{CH}_2\) groups

Shifts of the same order of magnitude occur for protons on \(\text{CH}_2\) groups and the proton on \(\text{CH}\) groups, but with the added complication that \(\text{CH}_2\) groups have two other substituents and \(\text{CH}\) groups three. A \(\text{CH}_2\) (methylene) group resonates at 1.3 p.p.m., about 0.4 p.p.m. further downfield than a comparable \(\text{CH}_3\) group (0.9 p.p.m.), and a \(\text{CH}\) (methine) group resonates at 1.7 p.p.m., another 0.4 p.p.m. downfield. Replacing each hydrogen atom in the \(\text{CH}_3\) group by a carbon atom causes a small downfield shift as carbon is slightly more electronegative (C 2.5 p.p.m.; H 2.2 p.p.m.) than hydrogen and therefore shields less effectively.

The benzyl group (PhCH\(_2\)–) is very important in organic chemistry. It occurs naturally in the amino acid phenylalanine, which you met in Chapter 2. Phenylalanine has its CH\(_2\) signal at 3.0 p.p.m. and is moved downfield from 1.3 p.p.m. mostly by the benzene ring.

Amino acids are often protected as the ‘Cbz’ derivatives (Carboxybenzyl) by reaction with an acid chloride.

Here is a simple example together with the NMR spectrum of the product. Now the CH\(_2\) group has gone further downfield to 5.1 p.p.m. as it is next to both oxygen and phenyl.

Like double bonds, cage structures prevent bond rotation, and can make the two protons of a CH\(_2\) group appear different. There are many flavouring compounds from herbs that have structures like this. In the example here—myrtenal, from the myrtle bush—there is a four-membered ring bridged across a six-membered ring. The CH\(_2\) group...
on the bridge has two different hydrogen atoms—one is over a methyl group and the other is over the enal system. No rotation of any bonds in the cage is possible, so these hydrogens are always different and resonate at different frequencies (1.04 and 2.49 p.p.m.). The methyl groups on the other bridge are also different for the same reason.

**Chemical shifts of CH groups**

A CH group in the middle of a carbon skeleton resonates at about 1.7 p.p.m.—another 0.4 p.p.m. downfield from a CH₂ group. It can have up to three substituents and these will cause further downfield shifts of about the same amount as we have already seen for CH₃ and CH₂ groups. Here are three examples from nature: nicotine, the compound in tobacco that causes the craving (though not the death, which is doled out instead by the carbon monoxide and tars in the smoke), has one hydrogen atom trapped between a simple tertiary amine and an aromatic ring at 3.24 p.p.m. Lactic acid has a CH proton at 4.3 p.p.m.. You could estimate this with reasonable accuracy by taking 1.7 (for the CH) and adding 1.0 (for C=O) plus 2.0 (for OH) = 4.7 p.p.m. Vitamin C (ascorbic acid) has two CHs. One at 4.05 p.p.m. is next to an OH group (estimate 1.7 + 2.0 for OH = 3.7 p.p.m.) and one next to a double bond and an oxygen atom at 4.52 p.p.m. (estimate 1.7 + 1 for double bond + 2 for OH = 4.7 p.p.m.).

An interesting case is the amino acid phenylalanine whose CH₂ group we looked at a moment ago. It also has a CH group between the amino and the carboxylic acid groups. If we record the ¹H NMR spectrum in D₂O, either in basic (NaOD) or acidic (DCl) solutions we see a large shift of that CH group. In basic solution the CH resonates at 3.60 p.p.m. and in acidic solution at 4.35 p.p.m. There is a double effect here: CO₂H and NH₃⁺ are both more electron-withdrawing than CO₂⁻ and NH₂ so both move the CH group downfield.

**Your simple guide to chemical shifts**

We suggest you start with a very simple (and therefore oversimplified) picture, which should be the basis for any further refinements. Start methyl groups at 0.9, methyl- enes (CH₃) at 1.3, and methines (CH) at 1.7 p.p.m. Any functional group is worth a one p.p.m. downfield shift except oxygen and halogen which are worth two p.p.m. This diagram summarizes the basic position.
This is a very rough and ready guide and you can make it slightly more accurate by adding subdivisions at 1.5 and 2.5 p.p.m. and including the very electron-withdrawing groups (nitro, ester, fluoro), which shift by 3 p.p.m. This gives us the summary chart on this page, which we suggest you use as a reference.

**Summary chart of proton NMR shifts**

values to be added to 0.9 for CH₃, 1.3 for CH₂ or 1.7 for CH
Answers deduced from this chart won’t be very accurate but will give a good guide. Remember—these shifts are additive. Take a simple example, the ketoester below. There are just three signals and the integration alone distinguishes the two methyl groups from the CH₂ group. One methyl has been shifted from 0.9 p.p.m. by about 1 p.p.m., the other by more than 2 p.p.m. The first must be next to C=O and the second next to oxygen. More precisely, 2.14 p.p.m. is a shift of 1.24 p.p.m. from our standard value (0.9 p.p.m.) for a methyl group, about what we expect for a methyl ketone, while 3.61 p.p.m. is a shift of 2.71 p.p.m., close to the expected 3.0 p.p.m. for an ester joined through the oxygen atom. The CH₂ group is next to an ester and a ketone carbonyl group and so we expect it at 1.3 + 1.0 + 1.0 = 3.3 p.p.m., an accurate estimate, as it happens. We shall return to these estimates when we look at spectra of unknown compounds.

The alkene region and the benzene region

In $^{13}$C NMR, one region was enough for both of these, but see how different things are with proton NMR.

The two carbon signals are almost the same (1.3 p.p.m. difference < 1% of the total 200 p.p.m. scale) but the proton signals are very different (1.6 p.p.m. difference = 16% of the 10 p.p.m. scale). There must be a fundamental reason for this.

The benzene ring current causes large shifts for aromatic protons

A simple alkene has an area of low electron density in the plane of the molecule because the $\pi$ orbital has a node there, and the carbons and hydrogen nuclei lying in the plane gain no shielding from the $\pi$ electrons.

The benzene ring looks similar at first sight, and the plane of the molecule is indeed a node for all the $\pi$ orbitals. However, benzene is ‘aromatic’—it has extra stability because the six $\pi$ electrons fit into three very stable orbitals and are delocalized round the whole ring.

The applied field sets up a ring current in these delocalized electrons that produces a local field rather like the field produced by the electrons around a nucleus. Inside the benzene ring, the induced field opposes the applied field but, outside the ring, it reinforces the applied field. The carbon atoms are in the ring itself and experience neither effect, but the hydrogens are outside the ring, feel a stronger applied field, and appear less shielded.

The alkene region and the benzene region
Uneven electron distribution in aromatic rings

The NMR spectrum of this simple aromatic amine has three peaks in the ratio 1:2:2 which must be 3H:6H:6H. The 6.38 p.p.m. signal clearly belongs to the protons round the benzene ring, but why are they at 6.38 and not at 7.27 p.p.m.? We must also distinguish the two methyl groups at 2.28 p.p.m. from those at 2.89 p.p.m. The chart on p. 000 suggests that these should both be at about 2.4 p.p.m., close enough to 2.28 p.p.m. but not to 2.89 p.p.m. The solution to both these puzzles is the distribution of electrons in the aromatic ring. Nitrogen feeds electrons into the \( \pi \) system making it electron-rich: the ring protons are more shielded and the nitrogen atom becomes positively charged and its methyl groups more deshielded. The peak at 2.89 p.p.m. belongs to the NMe2 group.

Other groups, such as simple alkyl groups, hardly perturb the aromatic system at all and it is quite common for all five protons in an alkyl benzene to appear as one signal instead of the three we might expect. Here is an example with some nonaromatic protons too: there is another on p. 000—the Cbz-protected amino acid.
The five protons on the aromatic ring all have the same chemical shift. The OCH₃ group is typical of a methyl ester (the chart on p. 000 gives 3.9 p.p.m.). One CH₂ group is between two carbonyl groups (cf. δ 3.35 p.p.m. for the similar CH₂ group on p. 000). The other is next to an ester and a benzene ring: we calculate 1.3 + 1.5 + 3.0 = 5.8 p.p.m. for that—reasonably close to the observed 5.19 p.p.m.

How electron donation and withdrawal change chemical shifts

We can get an idea of the effect of electron distribution by looking at a series of 1,4-disubstituted benzenes. This pattern makes all the remaining hydrogens in the ring the same. The compounds are listed in order of chemical shift: largest shift (lowest field) first. Benzene itself resonates at 7.27 p.p.m. Conjugation is shown by the usual curly arrows, and inductive effects by a straight arrow by the side of the group. Only one effect and one hydrogen atom are shown; in fact, both groups exert the same effect on all four identical hydrogen atoms.

**electron-withdrawing groups**

The largest shifts come from groups that withdraw electrons by conjugation. Nitro is the most powerful—this should not surprise you as we saw the same in nonaromatic compounds both in $^{13}$C and $^1$H NMR spectra. Then come the carbonyl groups and nitrile followed by the few groups showing simple inductive withdrawal. CF₃ is an important example of this kind of group—three fluorine atoms combine to exert a powerful effect.

**electron-donating and -withdrawing groups**

Conjugation, as discussed in Chapters 7 and 10, is felt through π bonds, while inductive effects are the effects of electron withdrawal or donation felt simply by polarization of the σ bonds of the molecule. See p. 000.
In the middle, around the position of benzene itself at $\delta$ 7.27 p.p.m., come the halogens whose inductive electron withdrawal and lone pair donation are nearly balanced.

**electron-donating groups**

Alkyl groups are weak inductive donors and at the smallest shift we have the groups that, on balance, donate electrons to the ring and increase the shielding at the carbon atoms. Amino is the best of these. So a nitrogen-based functional group (NO$_2$) is the best electron withdrawer while another (NH$_2$) is the best electron donor.

As far as the donors with lone pairs are concerned, two factors are important—the size of the lone pairs and the electronegativity of the element. If we look at the four halides (central box above) the lone pairs are in 2p(F), 3p(Cl), 4p(Br), and 5p(I) orbitals. In all cases the orbitals on the benzene ring are 2p so the fluorine orbital is of the right size and the others too large. Even though fluorine is the most electronegative, it is still the best donor.

Now comparing the groups in the first row of the p block elements. F, OH, NH$_2$, all have lone pairs in 2p orbitals so electronegativity is the only variable. As you would expect, the most electronegative element, F, is now the weakest donor.

**Electron-rich and electron-deficient alkenes**

The same sort of thing happens with alkenes. We’ll concentrate on cyclohexene so as to make a good comparison with benzene. The six identical protons of benzene resonate at 7.27 p.p.m.; the two identical alkene protons of cyclohexene resonate at 5.68 p.p.m. A conjugating and electron-withdrawing group such as a ketone removes electrons from the double bond as expected—but unequally. The proton nearer the C=O group is only slightly downfield from cyclohexene but the more distant one is over 1 p.p.m. downfield. The curly arrows show the electron distribution, which we can deduce from the NMR spectrum.

Oxygen as a conjugating electron donor is even more dramatic. It shifts the proton nearer to it downfield by the inductive effect but pushes the more distant proton upfield again by a whole p.p.m. by donating electrons. The separation between the two protons is nearly two p.p.m.

For both types of substituent, the effects are more marked on the more distant (β) proton. If these shifts reflect the true electron distribution, we can deduce that nucleophiles will attack the electron-deficient site in the nitroalkene, while electrophiles will be attacked by the electron-rich sites in silyl enol ethers and enamines. These are all important reagents and do indeed react as we predict, as you will see in later chapters. Look at the difference—there are nearly 3 p.p.m. between the nitro compound and the enamine!
Structural information from the alkene region

Alkene protons on different carbon atoms can obviously be different if the carbon atoms themselves are different and we have just seen examples of that. Alkene protons can also be different if they are on the same carbon atom. All that is necessary is that the substituents at the other end of the double bond should themselves be different. The silyl enol ether and the unsaturated ester below both fit into this category. The protons on the double bond must be different, because each is cis to a different group. The third compound is an interesting case: the different shifts of the two protons on the ring prove that the N–Cl bond is at an angle to the C=N bond. If it were in line, the two hydrogens would be identical. The other side of the C=N bond is occupied by a lone pair and the nitrogen atom is trigonal (sp² hybridized).

DMF is similar: as we saw earlier (p. 000), it has two different methyl groups because of the double bond.

The aldehyde region: unsaturated carbon bonded to oxygen

The aldehyde proton is unique. It is directly attached to a carbonyl group—one of the most electron-withdrawing groups that exists—and is very deshielded, resonating with the largest shifts of any CH protons in the 9–10 p.p.m. region. The examples below are all compounds that we have met before. Two are just simple aldehydes—aromatic and aliphatic. The third is the solvent DMF. ItsCHO proton is less deshielded than most—the amide delocalization that feeds electrons into the carbonyl group provides some extra shielding.

Aliphatic is a catch-all term for compounds that are not aromatic.

Conjugation with an oxygen atom has much the same effect—formate esters resonate at about 8 p.p.m.—but conjugation with π bonds does not. The simple conjugated aldehyde below and myrtenal both have CHO protons in the normal region (9–10 p.p.m.).
Two other types of protons resonate in this region: some aromatic protons and some protons attached to heteroatoms like OH and NH. The first of these will provide our discussion on structural information and the second will be the subject of the section following that discussion.

**Structural information from the aldehyde region**

Protons on double bonds, even very electron-deficient double bonds like those of nitroalkenes, hardly get into the aldehyde region. However, some benzene rings with very electron-withdrawing groups do manage it because of the extra downfield shift of the ring current, so beware of nitrobenzenes as they may have signals in the 8–9 p.p.m. region.

More important molecules with signals in this region are the aromatic heterocycles such as pyridine, which you met in Chapter 7. The NMR shifts clearly show that pyridine is aromatic and we discussed its basicity in Chapter 8. One proton is at 7.1 p.p.m., essentially the same as benzene, but the others are more downfield and one, at C2, is in the aldehyde region. This is not because pyridine is ‘more aromatic’ than benzene but because nitrogen is more electronegative than carbon. Position C2 is like an aldehyde—a proton attached to sp$^2$ C bearing a heteroatom—while C4 is electron-deficient by conjugation (the electronegative nitrogen is electron-withdrawing). Isoquinoline is a pyridine and a benzene ring fused together and has a proton even further downfield at 9.1 p.p.m.—this is an imine proton that experiences the ring current of the benzene ring.

**Protons on heteroatoms are more variable than protons on carbon**

Protons directly attached to O, N, or S (or any other heteroatom, but these are the most important) also have signals in the NMR spectrum. We have avoided them so far because the positions of these signals are less reliable and because they are affected by exchange.

In Chapter 3 we looked at the $^{13}$C NMR spectrum of BHT. Its proton NMR is very simple, consisting of just four lines with integrals 2, 1, 3, and 18. The chemical shifts of the $t$-butyl group, the methyl group on the benzene ring, and the two identical aromatic protons should cause you no surprise. What is left, the 1H signal at 5.0 p.p.m., must be the OH. Earlier on in this chapter we saw the spectrum of acetic acid CH$_3$CO$_2$H, which showed an OH resonance at 11.2 p.p.m. Simple alcohols such as $t$-butanol have OH signals in CDCl$_3$ (the usual NMR solvent) at around 2 p.p.m. Why such differences?
This is a matter of acidity. The more acidic a proton is—that is, the more easily it releases H⁺ (this is the definition of acidity from Chapter 8)—the more the OH bond is polarized towards oxygen. The more the RO–H bond is polarized, the closer we are to free H⁺, which would have no shielding electrons at all, and so the further the proton goes downfield. The OH chemical shifts and the acidity of the OH group are very roughly related.

Thiols (RSH) behave in a similar way to alcohols but are not so deshielded, as you would expect from the smaller electronegativity of sulfur (phenols are all about 5.0 p.p.m., PhSH is at 3.41 p.p.m.). Alkane thiols appear at about 2 p.p.m. and arylthiols at about 4 p.p.m. Amines and amides show a big variation, as you would expect for the variety of functional groups involved, and are summarized below. Amides are slightly acidic, as you saw in Chapter 8, and amide protons resonate at quite low fields. Pyrroles are special—the aromaticity of the ring makes the NH proton unusually acidic and they appear at about 10 p.p.m.

Exchange of acidic protons is revealed in proton NMR spectra

Compounds with very polar groups often dissolve best in water. NMR spectra are usually run in CDCl₃, but heavy water, D₂O, is an excellent NMR solvent. Here are some results in that medium.

EDTA is ethylenediamine tetraacetic acid, an important complexing agent for metals. This is the salt formed with just two equivalents of ammonia.
Glycine is expected to exist as a zwitterion (Chapter 8, p. 000). It has a 2H signal for the CH$_2$ between the two functional groups, which would do for either form. The 3H signal at 4.90 p.p.m. might suggest the NH$_3^+$ group, but wait a moment before making up your mind. The aminothiol salt has the CMe$_2$ and CH$_2$ groups about where we would expect them, but the SH and NH$_3^+$ protons appear as one 4H signal. The double salt of EDTA has several curious features. The two CH$_2$ groups in the middle are fine, but the other four CH$_2$ groups all appear identical as do all the protons on both the CO$_2$H and NH$_3^+$ groups.

The best clue to why this is so involves the chemical shifts of the OH, NH, and SH protons in these molecules. They are all the same within experimental error: 4.90 p.p.m. for glycine, 4.80 p.p.m. for the aminothiol, and 4.84 p.p.m. for EDTA. They all correspond to the same species: HOD. Exchange between XH (where X = O, N, or S) protons is extremely fast, and the solvent, D$_2$O, supplies a vast excess of exchangeable deuteriums. These immediately replace all the OH, NH, and SH protons in the molecules with D, forming HOD in the process. Recall that we do not see signals for deuterium atoms (that’s why deuterated solvents are used). They have their own spectra at a different frequency.

The same sort of exchange between OH or NH protons with each other or with traces of water in the sample means that the OH and NH peaks in most spectra in CDCl$_3$ are rather broader than the peaks for CH protons.

Two questions remain. First, can we tell whether glycine is a zwitterion in water or not? Not really: the spectra fit either or an equilibrium between both. Other evidence leads us to prefer the zwitterion in water. Second, why are all four CH$_2$CO groups in EDTA the same? This we can answer. As well as the equilibrium exchanging the CO$_2$H protons with the solvent, there will be an equally fast equilibrium exchanging protons between CO$_2$H and CO$_2$D. This makes all four ‘arms’ of EDTA the same.

You should leave this section with an important chemical principle firmly established in your mind.

**Protons exchange fast**

Proton exchange between heteroatoms, particularly O, N, and S, is a *very fast* process in comparison with other chemical reactions, and often leads to averaged peaks in the $^1$H NMR spectrum.

You will need this insight as you study organic mechanisms.

### Coupling in the proton NMR spectrum

**Nearby hydrogen nuclei interact and give multiple peaks**

So far proton NMR has been not unlike carbon NMR on a smaller scale. However, we have yet to discuss the real strength of proton NMR, something more important than chemical shifts and
something that allows us to look not just at individual atoms but also at the way the C–H skeleton is joined together. This is the result of the interaction between nearby protons known as coupling.

An example we could have chosen in the last section is the nucleic acid component, cytosine, which has exchanging NH$_2$ and NH protons giving a peak for HDO at 4.5 p.p.m. We didn’t choose this example because the other two peaks would have puzzled you. Instead of giving just one line each, they give two lines each—doublets as you will learn to call them—and it is time to discuss the origin of this ‘coupling’.

You might have expected a spectrum like that of the heterocycle below, which is also a pyrimidine. It too has exchanging NH$_2$ protons and two protons on the heterocyclic ring. But these two protons give the expected two lines instead of the four lines in the cytosine spectrum. It is easy to assign the spectrum: proton H$^A$ is attached to an aldehyde-like C=N and so comes at lowest field. The proton H$^X$ is ortho to two electron-donating NH$_2$ groups and so comes at high field for an aromatic proton (p. 000). These protons do not couple with each other because they are too far apart. They are separated by five bonds whereas the ring protons in cytosine are separated by just three bonds.

Understanding this phenomenon is so important that we are going to explain it in three different ways—you choose which appeals to you most. Each method offers a different insight.

The pyrimidine spectrum has two single lines (singlets we shall call them from now on) because each proton, H$^A$ or H$^X$, can be aligned either with or against the applied magnetic field. The cytosine spectrum is different because each proton, say, H$^A$, is near enough to experience the small magnetic field of the other proton H$^X$ as well as the field of the magnet itself. The diagram shows the result.
If each proton interacted only with the applied field we would get two singlets. But proton H^A actually experiences two slightly different fields: the applied field plus the field of H^X or the applied field minus the field of H^X. H^X acts either to increase or to decrease the field experienced by H^A. The position of a resonance depends on the field experienced by the proton so these two situations give rise to two slightly different peak—a doublet as we shall call it. And whatever happens to H^A happens to H^X as well, so the spectrum has two doublets, one for each proton. Each couples with the other. The field of a proton is a very small indeed in comparison with the field of the magnet and the separation between the lines of a doublet is very small. We shall discuss the size of the coupling later (p. 000).

The second explanation takes into account the energy levels of the nucleus. In Chapter 4, when we discussed chemical bonds, we imagined electronic energy levels on neighbouring atoms interacting with each other and splitting to produce new molecular energy levels, some higher in energy and some lower in energy than the original atomic energy levels. When hydrogen nuclei are near each other in a molecule, the nuclear energy levels also interact and split and produce new energy levels. If a single hydrogen nucleus interacts with a magnetic field, we have the picture on p. 000 of this chapter: there are two energy levels as the nucleus can be aligned with or against the applied magnetic field, there is one energy jump possible, and there is a resonance at one frequency. This you have now seen many times and it can be summarized as shown below.
The spectrum of the pyrimidine on p. 000 showed two protons each independently in this situation. Each had two energy levels, each gave a singlet, and there were two lines in the spectrum. But, in the cytosine molecule, each proton has another hydrogen nucleus nearby and there are now four energy levels. Each nucleus $H^A$ and $H^X$ can be aligned with or against the applied field. There is one most stable energy level where they are both aligned with the field and one least stable level where they are both aligned against. In between there are two different energy levels in which one nucleus is aligned with the field and one against. Exciting $H^A$ from alignment with to alignment against the applied field can be done in two slightly different ways, shown as $A_1$ and $A_2$ on the diagram. The result is two resonances very close together in the spectrum.

### energy levels for two interacting nuclei $H^A$ and $H^X$

- **$A_1$:** energy required to excite $A$ with $X$ but against $B_0$.
- **$A_2$:** energy required to excite $A$ with $X$ but against $B_0$.
- **$X_1$:** energy required to excite $X$ against $A$ and against $B_0$.
- **$X_2$:** energy required to excite $X$ with $A$ but against $B_0$.

Please notice carefully that we cannot have this discussion about $H^A$ without discussing $H^X$ in the same way. If there are two slightly different energy jumps to excite $H^A$, there must also be two slightly different energy jumps to excite $H^X$. The difference between $A_1$ and $A_2$ is exactly the same as the difference between $X_1$ and $X_2$. Each proton now gives two lines (a doublet) in the NMR spectrum and the splitting of the two doublets is exactly the same. We describe this situation as *coupling*. We say 'A and X are coupled' or 'X is coupled to A'(and vice versa, of course). We shall be using this language from now on and so must you.

Now look back at the spectrum of cytosine at the beginning of this section. You can see the two doublets, one for each of the protons on the aromatic ring. Each is split by the same amount (this is easy to check with a ruler) and the separation of the lines is the *coupling constant* and is called $J$. In this case $J = 4$ Hz. Why do we measure $J$ in hertz and not in p.p.m.? We measure chemical shifts in p.p.m. because we get the same number regardless of the rating of the NMR machine in MHz. We measure $J$ in Hz because we also get the same number regardless of the machine.
Now for the third way to describe coupling. If you look again at what the spectrum would be like without interaction between $H^A$ and $H^X$ you would see this, with the chemical shift of each proton clearly obvious.

But you don’t see this because each proton couples with the other and splits its signal by an equal amount either side of the true chemical shift.

The true spectrum has a pair of doublets each split by an identical amount. Note that no line appears at the true chemical shift, but it is easy to measure the chemical shift by taking the midpoint of the doublet.
So this spectrum would be described as $\delta_H$ 7.5 (1H, d, $J$ 4 Hz, HA) and 5.8 (1H, d, $J$ 4 Hz, HX). The main number gives the chemical shift in p.p.m. and then, in brackets, comes the integration as the number of Hs, the shape of the signal (here ‘d’ for doublet), the size of coupling constants in Hz, and the assignment, usually related to a diagram. The integration refers to the combined integral of both peaks in the doublet. If the doublet is exactly symmetrical, each peak integrates to half a proton. The combined signal, however complicated, integrates to the right number of protons.

We have described these protons as A and X with a purpose in mind. A spectrum of two equal doublets is called an **AX spectrum**. A is always the proton you are discussing and X is a proton with a very different chemical shift. The alphabet is used as a ruler: nearby protons (on the chemical shift scale—not necessarily nearby in the structure!) are called B, C, etc. and distant ones are called X, Y, etc. You will see the reason for this soon.

If there are more protons involved, the splitting process continues. Here is the NMR spectrum of a famous perfumery compound supposed to have the smell of ‘green leaf lilac’. The compound is an acetal with five nearly identical aromatic protons at the normal benzene position (7.2–7.3 p.p.m.) and six protons on two identical OMe groups.

It is the remaining three protons that interest us. They appear as a 2H doublet at 2.9 p.p.m. and a 1H triplet at 4.6 p.p.m. In NMR talk, **triplet** means three equally spaced lines in the ratio 1:2:1. The triplet arises from the three possible states of the two identical protons in the CH$_2$ group.

If one proton H$^A$ interacts with two protons H$^X$, it can experience three states of proton H$^X$. Both protons H$^X$ can be aligned with the magnet or both against. These states will increase or decrease the applied field just as before. But if one proton H$^X$ is aligned with, and one against the applied field, there is no net change to the field experienced by H$^A$ and there are two possibilities for this (see diagram). We therefore see a signal of double intensity for H$^A$ at the correct chemical shift, one signal at higher field and one at lower field. In other words, a 1:2:1 triplet.
We could look at this result by our other methods too. There is one way in which both nuclei can be aligned with and one way in which both can be aligned against the applied field, but two ways in which they can be aligned one with and one against. Proton $H^A$ interacts with each of these states. The result is a 1:2:1 triplet.
Using our third way to see how the triplet arises, we can look at the splitting as it happens.

If there are more protons involved, we continue to get more complex systems, but the intensities can all be deduced simply from Pascal’s triangle, which gives the coefficients in a binomial expansion. If you are unfamiliar with this simple device, here it is.

You can read off from the triangle what pattern you may expect when a proton is coupled to \( n \) equivalent neighbours. There are always \( n+1 \) peaks with the intensities shown by the triangle. So far, you’ve seen 1:1 doublets (line 2 of the triangle) from coupling to 1 proton, and 1:2:1 triplets (line 3) from coupling to 2. You will often meet ethyl groups (CH₃–CH₂X) where the CH₂ group appears as a 1:3:3:1 quartet and the methyl group as a 1:2:1 triplet and isopropyl groups (CH₃)₂CHX where the methyl groups appear as a 6H doublet and the CH group as a septuplet. The outside lines of a septuplet are so weak (1/20th of the middle line) that it is often mistaken for a quintet. Inspection of the integral should put you on the right track.

Here is a simple example, the four-membered cyclic ether oxetane. Its NMR spectrum has a 4H triplet for the two identical CH₂ groups next to oxygen and a 2H quintet for the CH₂ in the middle. Each proton H^X ‘sees’ four identical neighbours (H^A) and is split equally by them all to give a
1:4:6:4:1 quintet. Each proton $H^A$ ‘sees’ two identical neighbours $H^X$ and is split into a 1:2:1 triplet. The combined integral of all the lines in the quintet together is 2 and of all the lines in the triplet is 4.

A slightly more complicated example is the diethyl acetal below. It has a simple AX pair of doublets for the two protons on the ‘backbone’ (red and green) and a typical ethyl group (2H quartet and 3H triplet). An ethyl group is attached to only one substituent through its CH$_2$ group, so the chemical shift of that CH$_2$ group tells us what it is joined to. Here the peak at 3.76 p.p.m. can only be an OEt group. There are, of course, two identical CH$_2$ groups in this molecule.

So far, we have seen situations where a proton has several neighbours, but the coupling constants to all the neighbours have been the same. What happens when coupling constants differ? Chrysanthemic acid, the structural heart of the natural pyrethrin insecticides, gives an example of the simplest situation—where a proton has two different neighbours.
This is an interesting three-membered ring compound produced by pyrethrum flowers (Chapter 1). It has a carboxylic acid, an alkene, and two methyl groups on the three-membered ring. Proton $H^A$ has two neighbours, $H^X$ and $H^M$. The coupling constant to $H^X$ is 8 Hz, and that to $H^M$ is 5.5 Hz. The splitting pattern looks like this.

### Abbreviations used for style of signal

| m            | multiplet | avoid if possible but sometimes necessary to describe complicated signals |

The result is four lines of equal intensity called a double doublet (or sometimes a doublet of doublets), abbreviation dd. The smaller coupling constant can be read off from the separation between lines 1 and 2 or between lines 3 and 4, while the larger coupling constant is between lines 1 and 3 or between lines 2 and 4. You could see this as an imperfect triplet where the second coupling is too small to bring the central lines together; alternatively, look at a triplet as a special case of a double doublet where the two couplings are identical.

### Coupling is a through bond effect

Neighbouring nuclei might interact through space or through the electrons in the bonds. We know that coupling is in fact a ‘through bond effect’ because of the way coupling constants vary with the shape of the molecule. The most important case occurs when the protons are at either end of a double bond. If the two hydrogens are cis, the coupling constant $J$ is typically about 10 Hz but, if they are trans, $J$ is much larger, usually 15–18 Hz. These two chloro acids are good examples.

If coupling were through space, the nearer cis hydrogens would have the larger $J$. In fact, coupling occurs through the bonds and the more perfect parallel alignment of the orbitals in the trans compound provides better communication and a larger $J$.

Coupling is at least as helpful as chemical shift in assigning spectra. When we said that the protons on cyclohexone had the chemical shifts shown, how did we know? It was coupling that told us the answer. The proton next to the carbonyl group has one neighbour and appears as a doublet with $J = 11$ Hz, just right for a proton on a double bond with a cis neighbour. The proton at the other end appears as a double triplet. Inside each triplet the separation of the lines is 4 Hz and the two triplets are 11 Hz apart. This means the following diagrammatically.

For the same reason—orbital overlap—this anti arrangement of substituents is also preferred in chemical reactions such as elimination (Chapter 19) and fragmentation (Chapter 38).
This is what happens when a proton couples to different groups of protons with different coupling constants. Many different coupling patterns are possible, many can be interpreted, but others cannot. However, machines with high field magnets make the interpretation easier. As a demonstration, let us turn back to the bee alarm pheromone that we met in Chapter 3. An old 90 MHz NMR spectrum of this compound looks like this.

![Spectrum](image)

You can see the singlet for the isolated black methyl group and just about make out the triplets for the green CH₂ group next to the ketone (C3) at about 2.5 p.p.m. and for the orange methyl group at 0.9 p.p.m. (C7) though this is rather broad. The rest is frankly a mess. Now see what happens when the spectrum is run on a more modern 500 MHz spectrometer.

![Spectrum](image)

Notice first of all that the chemical shifts have not changed. However, all the peaks have closed up. This is because \( J \) stays the same in Hz and the 7 Hz coupling for the methyl group triplet was \( 7/90 = 0.07 \) p.p.m. at 90 MHz but is \( 7/500 = 0.014 \) p.p.m. at 500 MHz. In the high field spectrum you can easily see the singlet and the two triplets but you can also see a clear quintet for the red CH₂ group at C4, which couples to both neighbouring CH₂ groups with the same \( J \) (7 Hz). Only the two CH₂ groups at C5 and C6 are not resolved. However, this does not matter as we know they are there from the coupling pattern. The triplet for the orange methyl group at C7 shows that it is next to a CH₂ group, and the quintet for the CH₂ group at C4 shows that it is next to two CH₂ groups. We know about one of them, at C5, so we can infer the other at C6.
Coupling constants depend on three factors

In heptanone all the coupling constants were about the same but in cyclohexenone they were quite different. What determines the size of the coupling constant? There are three factors.

- Through bond distance between the protons
- Angle between the two C–H bonds
- Electronegative substituents

The coupling constants we have seen so far are all between hydrogen atoms on neighbouring carbon atoms. The coupling is through three bonds (H–C–C–H) and is designated $^3J_{HH}$. These coupling constants $^3J_{HH}$ are usually about 7 Hz in an open-chain, freely rotating system such as we have in heptanone. The C–H bonds vary little in length but the C–C bond might be a single or a double bond. In cyclohexenone it is a double bond, significantly shorter than a single bond. Couplings ($^3J_{HH}$) across double bonds are usually larger than 7 Hz (11 Hz in cyclohexenone). $^3J_{HH}$ couplings are called vicinal couplings because the protons concerned are on neighbouring carbon atoms.

Something else is different too: in an open-chain system we have a time average of all rotational conformations. Across a double bond there is no rotation and the angle between the two C–H bonds is fixed because they are in the same plane. In the plane of the alkene, the C–H bonds are either at 60° (cis) or at 180° (trans) to each other. Coupling constants in benzene rings are slightly less than those across cis alkenes because the bond is longer (bond order 1.5 rather than 2).

In naphthalenes, there are unequal bond lengths around the two rings. The bond between the two rings is the shortest, and the lengths of the others are shown. Coupling across the shorter bond (8 Hz) is significantly stronger than coupling across the longer bond (6.5 Hz).

The effect of the third factor, electronegativity, is easily seen in the comparison between ordinary alkenes and enol ethers. We are going to compare two series of compounds with a cis or a trans double bond. One series has a phenyl group at one end of the alkene and the other has an OPh group. Within each box, that is for either series, the trans coupling is larger than the cis, as you would now expect. But if you compare the two series, the enol ethers have much smaller coupling constants. The trans coupling for the enol ethers is only just larger than the cis coupling for the alkenes. The electronegative oxygen atom is withdrawing electrons from the C–H bond in the enol ethers and weakening communication through the bonds.

Effect of electronegative substituents on $^3J_{HH} –$ alkenes and enol ethers

**Alkenes**

- $^3J_{cis} = 11.5$ Hz
- $^3J_{trans} = 16.0$ Hz

**Enol ethers**

- $^3J_{cis} = 6.0$ Hz
- $^3J_{trans} = 12.0$ Hz
Another good example is the coupling found in pyridines. Though the bond order is actually slightly less between C3 and C4, the coupling constants are about normal for an aromatic ring (compare naphthalene above), while coupling constants across C2 and C3, nearer to the electronegative nitrogen, are smaller.

When the through bond distance gets longer, coupling is not usually seen. To put it another way, four-bond coupling $J_{HH}$ is usually zero. However, it is seen in some special cases, the most important being meta coupling in aromatic rings and allylic coupling in alkenes. In both, the orbitals between the two hydrogen atoms can line up in a zig-zag fashion to maximize interaction. This arrangement looks rather like a letter ‘W’ and this sort of coupling is called W-coupling. Even with this advantage, values of $J_{HH}$ are usually small, about 1–3 Hz.

Meta coupling is very common when there is ortho coupling as well, but here is an example where there is no ortho coupling because none of the aromatic protons have immediate neighbours—the only coupling is meta coupling. There are two identical HAs, which have one meta neighbour and appear as a 2H doublet. Proton HX between the two MeO groups has two identical meta neighbours and so appears as a 1H triplet. The coupling is small ($J \sim 2.5$ Hz).

We have already seen a molecule with allylic coupling. We discussed in some detail why cyclohexenone has a double triplet for H3. But it also has a less obvious double triplet for H2. The triplet coupling is less obvious because $J$ is small (about 2 Hz) because it is $J_{HH}$—allylic coupling to the CH2 group at C4. Here is a diagram of the coupling, which you should compare with the earlier one for cyclohexenone.

**Coupling between similar protons**

We have already seen that identical protons do not couple with each other. The three protons in a methyl group may couple to some other protons, but never couple with each other. They are an $A_3$ system. Identical neighbours do not couple either. In the para-disubstituted benzenes we saw on p. 000, all the protons on the aromatic rings were singlets.
We have also seen how two different protons forming an AX system give two separate doublets. Now we need to see what happens to protons in between these two extremes. What happens to two similar neighbours? Do the two doublets of the AX system suddenly collapse to the singlet of the A2 system? You have probably guessed that they do not. The transition is gradual. Suppose we have two different neighbours on an aromatic ring. The spectra show what we see.

The critical factor is how the difference between the chemical shifts of the two protons (Δδ) compares with the size of the coupling constant (J) for the machine in question. If Δδ is much larger than J there is no distortion: if, say, Δδ is 4 p.p.m. at 250 MHz (= 1000 Hz) and the coupling constant is a normal 7 Hz, then this condition is fulfilled and we have an AX spectrum of two 1:1 doublets. As Δδ approaches J in size, so the inner lines of the two doublets increase and the outer lines decrease until, when Δδ is zero, the outer lines vanish away altogether and we are left with the two superimposed inner lines—a singlet or an A2 spectrum. You can see this progression in the diagram.
We call the last stages, where the distortion is great but the protons are still different, an **AB spectrum** because you cannot really talk about H^A without also talking about H^B. The two inner lines may be closer than the gap between the doublets, or the four lines may all be equally spaced. Two versions of an AB spectrum are shown in the diagram—there are many more variations.

It is a generally useful tip that a distorted doublet 'points' towards the protons with which it is coupled.

Or, to put it another way, the AB system is ‘roofed’ with the usual arrangement of low walls and a high middle to the roof. Look out for doublets (or any other coupled signals) of this kind.

We shall end this section with a final example illustrating *para*-disubstituted benzenes and roofing as well as an ABX system and an isopropyl group.

The aromatic ring protons form a pair of distorted doublets (2H each) showing that the compound is a *para*-disubstituted benzene. Then the alkene protons form the AB part of an ABX spectrum. They are coupled to each other with a large (*trans*) \( J = 16 \text{ Hz} \) and one is also coupled to another distant proton. The large doublets are distorted (AB) but the small doublets within the right-hand half of the AB system are equal in height. The distant proton X is part of an *i*-Pr group and is coupled to H^B and the six identical methyl protons. Both \( J \)s are nearly the same so it is split by seven protons and is an octuplet. It looks like a sextuplet because the intensity ratios of the lines in an octuplet would be 1:7:21:35:35:21:7:1 (from Pascal’s triangle) and it is hardly surprising that the outside lines disappear.

**Coupling can occur between protons on the same carbon atom**

We have seen cases where protons on the same carbon atom are different: compounds with an alkene unsubstituted at one end. If these protons are different (and they are certainly near to each other), then they should couple. They do, but in this case the coupling constant is usually very small. Here you see the example we met on p. 000.
The small 1.4 Hz coupling is a $^{2}J_{JJ}$ coupling between two protons on the same carbon that are different because there is no rotation about the double bond. $^{2}J_{JJ}$ coupling is called geminal coupling.

This means that a monosubstituted alkene will have very characteristic signals for the three protons on the double bond. The three different coupling constants are very different so that this ABX system is unusually clear.

Here is an example of such a vinyl compound, ethyl acrylate (ethyl propenoate, a monomer for the formation of acrylic polymers). The spectrum looks rather complex at first, but it is easy to sort out using the coupling constants.

The largest $J$ (16 Hz) is obviously between X and B (trans coupling), the medium $J$ (10 Hz) is between X and A (cis coupling), and the small $J$ (4 Hz) must be between A and B (geminal). This assigns all the protons: A, 5.80 p.p.m.; B, 6.40 p.p.m.; X, 6.11 p.p.m. Rather surprisingly, X comes between A and B in chemical shift. Assignments based on coupling are more reliable than those based on chemical shift alone.

An enol ether type of vinyl group is present in ethyl vinyl ether, a reagent used for the protection of alcohols. This time all the coupling constants are smaller because of the electronegativity of the oxygen atom, which is now joined directly to the double bond.

It is still a simple matter to assign the protons of the vinyl group because couplings of 13, 7, and 2 Hz must be trans, cis, and geminal, respectively. In addition, X is on a carbon atom next to oxygen and so goes downfield while A and B have extra shielding from the conjugation of the oxygen lone pairs (see p. 000).

Geminal coupling on saturated carbons can be seen only if the hydrogens of a CH$_2$ group are different. We have seen an example of this on the bridging CH$_2$ group of myrtenal (p. 000).
coupling constant for the protons on the bridge, $J_{AB}$, is 9 Hz. Geminal coupling constants in a saturated system can be much larger (typically 10–16 Hz) than in an unsaturated one.

### To conclude

You have now met, in Chapter 3 and this chapter, all of the most important spectroscopic techniques available for working out the structure of organic molecules. We hope you can now appreciate that proton NMR is by far the most powerful of these techniques, and we hope you will be referring back to this chapter as you read the rest of the book. We shall talk about proton NMR a lot, and specifically we will come back to it in detail in Chapter 15, where we will look at using all of the spectroscopic techniques in combination, and in Chapter 32, when we look at what NMR can tell us about the shape of molecules.
1. How many signals will there be in the $^1$H NMR spectrum of each of these compounds? Estimate the chemical shifts of the signals.

2. Comment on the chemical shifts of these three compounds and suggest whether there is a worthwhile correlation with $pK_a$.

<table>
<thead>

3. One isomer of dimethoxybenzoic acid has the $^1$H NMR spectrum 3.85 (6H, s), 6.63 (1H, t, $J$ 2 Hz), 7.17 (2H, d, $J$ 2 Hz) and one isomer of coumalic acid has the $^1$H NMR spectrum 6.41 (1H, d, $J$ 10 Hz), 7.82 (1H, dd, $J$ 2, 10 Hz), 8.51 (1H, d, $J$ 2 Hz). In each case, which isomer is it? The substituents in black can be on any carbon atoms.

4. Assign the NMR spectra of this compound (assign means say which signal belongs to which atom) and justify your assignments.

5. Assign the $^1$H NMR spectra of these compounds and explain the multiplicity of the signals.

6. The reaction below was expected to give product 6A and did indeed give a product with the correct molecular formula by mass spectrometry. The $^1$H NMR spectrum of the product was however: $\delta_H$ (p.p.m.) 1.27 (6H, s), 1.70 (4H, m), 2.88 (2H, m), 5.4–6.1 (2H, broad s, exchanges with D$_2$O), 7.0–7.5 (3H, m). Though the detail is missing from this spectrum, how can you already tell that this is not the compound expected?

7. Assign the 400 MHz $^1$H NMR spectrum of this enynone as far as possible, justifying both chemical shifts and coupling patterns.
8. A nitration product (C₈H₁₁N₃O₂) of this pyridine has been isolated which has a nitro (NO₂) group somewhere on the molecule. From the 90 MHz ¹H NMR spectrum, deduce whether the nitro group is (a) on the ring, (b) on the NH nitrogen atom, or (c) on the aliphatic side chain and then exactly where it is. Give a full analysis of the spectrum.

![Nitration product structure](image)

9. The natural product bullatenone was isolated in the 1950s from a New Zealand myrtle and assigned the structure 9A. Then compound 9A was synthesized and found not to be identical with natural bullatenone. Predict the expected ¹H NMR spectrum of 9A. Given the full spectroscopic data available nowadays, but not in the 1950s, say why 9A is definitely wrong and suggest a better structure for bullatenone.

Spectra of bullatenone:
- Mass spectrum: m/z 188 (10%) (high resolution confirms C₁₂H₁₂O₂), 105 (20%), 102 (100%), and 77 (20%).
- Infrared: 1604 and 1705 cm⁻¹.
- ¹H NMR: 1.45 (6H, s), 5.82 (1H, s), 7.35 (3H, m), and 7.68 (2H, m).

10. Interpret this ¹H NMR spectrum.

![Interpreted spectrum](image)

11. Suggest structures for the products of these reactions, interpreting the spectroscopic data. You are not expected to write mechanisms for the reactions and you should resist the temptation to work out what ‘should happen’ from the reactions. These are all unexpected products.

![Reaction schemes](image)

12. Precocene is an compound that causes insect larvae to pupate and can also be found in some plants (Ageratum spp.) where it may act as an insecticide. It was isolated in minute amounts and has the following spectroscopic details. Propose a structure for precocene.

Spectra of precocene:
- Mass spectrum: m/z (high resolution gives C₁₃H₁₆O₃), M—15 (100%) and M—30 (weak).
- Infrared: CH and fingerprint only.
- ¹H NMR: 1.34 (6H, s), 3.80 (3H, s), 3.82 (3H, s), 5.54 (1H, d, J₁0 Hz), 6.37 (1H, d, J₁0 Hz), 6.42 (1H, s), and 6.58 (1H, s).

13. Suggest structures for the products of these reactions, interpreting the spectroscopic data. Though these products, unlike those in Problem 11, are reasonably logical, you will not meet the mechanisms for the reactions until Chapters 22, 29, and 23, respectively, and you are advised to solve the structures through the spectra.
14. The following reaction between a phosphonium salt, base, and an aldehyde gives a hydrocarbon $C_6H_{12}$ with the 200 MHz $^1H$ NMR spectrum shown. Give a structure for the product and comment on its stereochemistry. You are not expected to discuss the chemistry!
Nucleophilic substitution at the carbonyl (C=O) group

- Reactions of enols ch21, ch26-ch29
- Synthesis in action ch25

You are already familiar with reactions of compounds containing carbonyl groups. Aldehydes and ketones react with nucleophiles at the carbon atom of their carbonyl group to give products containing hydroxyl groups. Because the carbonyl group is such a good electrophile, it reacts with a wide range of different nucleophiles: you have met reactions of aldehydes and ketones with (in Chapter 6) cyanide, water, alcohols, and (in Chapter 9) organometallic reagents (organolithiums and organomagnesiums, or Grignard reagents).

In this chapter and Chapter 14 we shall look at some more reactions of the carbonyl group—and revisit some of the ones we touched on in Chapter 6. It is a tribute to the importance of this functional group in organic chemistry that we have devoted four chapters of this book to its reactions. Just like the reactions in Chapters 6 and 9, the reactions in Chapters 12 and 14 all involve attack of a nucleophile on a carbonyl group. The difference will be that this step is followed by other mechanistic steps, which means that the overall reactions are not just additions but also substitutions.

The product of nucleophilic addition to a carbonyl group is not always a stable compound

Addition of a Grignard reagent to an aldehyde or ketone gives a stable alkoxide, which can be protonated with acid to produce an alcohol (you met this reaction in Chapter 9).

The same is not true for addition of an alcohol to a carbonyl group in the presence of base—in Chapter 6 we drew a reversible, equilibrium arrow for this transformation and said that the product, a hemiacetal, is only formed to a significant extent if it is cyclic.

The reason for this instability is that RO$^-$ is easily expelled from the molecule. We call groups that can be expelled from molecules, usually taking with them a negative charge, leaving groups. We'll look at leaving groups in more detail later in this chapter and again in Chapter 17.
So, if the nucleophile is also a leaving group, there is a chance that it will be lost again and that the carbonyl group will reform—in other words, the reaction will be reversible. The energy released in forming the C=O bond (bond strength 720 kJ mol⁻¹) more than makes up for the loss of two C–O single bonds (about 350 kJ mol⁻¹ each), one of the reasons for the instability of the hemiacetal product in this case.

Again, it collapses with loss of RO⁻ as a leaving group. This time, though, we have not gone back to starting materials: instead we have made a new compound (a ketone) by a substitution reaction—the OR group of the starting material has been substituted by the Me group of the product. In fact, as we shall see later, this reaction does not stop at this point because the ketone product can react with the Grignard reagent a second time.

### Carboxylic acid derivatives

Most of the starting materials for, and products of, these substitutions will be carboxylic acid derivatives, with the general formula RCOX. You met the most important members of this class in Chapter 3: here they are again as a reminder.

<table>
<thead>

*aWe shall use these two terms interchangeably.*

### Acid chlorides and acid anhydrides react with alcohols to make esters

Acetyl chloride will react with an alcohol in the presence of a base to give an acetate ester and we get the same product if we use acetic anhydride.

In each case, a substitution (of the black part of the molecule, Cl⁻ or AcO⁻, by the orange cyclohexanol) has taken place—but how? It is important that you learn not only the fact that...
acyl chlorides and acid anhydrides react with alcohols but also the *mechanism* of the reaction. In this chapter you will meet a lot of reactions, but relatively few mechanisms—once you understand one, you should find that the rest follow on quite logically.

The first step of the reaction is, as you might expect, addition of the nucleophilic alcohol to the electrophilic carbonyl group—we’ll take the acyl chloride first.

The base is important because it removes the proton from the alcohol as it attacks the carbonyl group. A base commonly used for this is pyridine. If the electrophile had been an aldehyde or a ketone, we would have got an unstable hemiacetal, which would collapse back to starting materials by eliminating the alcohol. With an acyl chloride, the alkoxide intermediate we get is also unstable. It collapses again by an elimination reaction, this time losing chloride ion, and forming the ester. Chloride is the *leaving group* here—it leaves with its negative charge.

With this reaction as a model, you should be able to work out the mechanism of ester formation from acetic anhydride and cyclohexanol. Try to write it down without looking at the acyl chloride mechanism above, and certainly not at the answer below. Here it is, with pyridine as the base. Again, addition of the nucleophile gives an unstable intermediate, which undergoes an elimination reaction, this time losing a carboxylate anion, to give an ester.

We call the unstable intermediate formed in these reactions the *tetrahedral intermediate*, because the trigonal (sp²) carbon atom of the carbonyl group has become a tetrahedral (sp³) carbon atom.

---

**Tetrahedral intermediates**

Substitutions at trigonal carbonyl groups go through a tetrahedral intermediate and then on to a trigonal product.

---

You will notice that the terms ‘acid chloride’ and ‘acyl chloride’ are used interchangeably.
How do we know that the tetrahedral intermediate exists?

We don’t expect you to be satisfied with the bland statement that tetrahedral intermediates are formed in these reactions; of course, you wonder how we know that this is true. The first evidence for tetrahedral intermediates in the substitution reactions of carboxylic acid derivatives was provided by Bender in 1951. He reacted water with carboxylic acid derivatives \( RCOX \) that had been ‘labelled’ with an isotope of oxygen, \( ^{18}O \). He then reacted these derivatives with water to make labelled carboxylic acids. However, he added insufficient water for complete consumption of the starting material. At the end of the reaction, he found that the proportion of labelled molecules in the remaining starting material had decreased significantly: in other words, it was no longer completely labelled with \( ^{18}O \); some contained ‘normal’ \( ^{16}O \).

This result cannot be explained by direct substitution of \( X \) by \( H_2O \), but is consistent with the existence of an intermediate in which the unlabelled \( ^{16}O \) and labelled \( ^{18}O \) can ‘change places’. This intermediate is the tetrahedral intermediate for this reaction.

The observant among you may also have noticed that the (weak—pyridine) base catalyst in this reaction works very slightly differently from the (strong—hydroxide) base catalyst in the hemiacetal-forming reaction on p. 000: one removes the proton after the nucleophile has added; the other removes the proton before the nucleophile has added. This is deliberate, and will be discussed further in Chapter 13.

Why are the tetrahedral intermediates unstable?

The alkoxide formed by addition of a Grignard reagent to an aldehyde or ketone is stable. Tetrahedral intermediates are similarly formed by addition of a nucleophile to a carbonyl group, so why are they unstable? The answer is to do with leaving group ability.
Once the nucleophile has added to the carbonyl compound, the stability of the product (or tetrahedral intermediate) depends on how good the groups attached to the new tetrahedral carbon atom are at leaving with the negative charge. In order for the tetrahedral intermediate to collapse (and therefore be just an intermediate and not the final product) one of the groups has to be able to leave and carry off the negative charge from the alkoxide anion formed in the addition.

Here once again is the tetrahedral intermediate resulting from addition of an alcohol to an acyl chloride.

There are three choices of leaving group: Cl\(^-\), EtO\(^-\), and Me\(^-\). We cannot actually make Me\(^-\) because it is so unstable, but MeLi, which is about as close to it as we can get (Chapter 9), reacts vigorously with water so Me\(^-\) must be a very bad leaving group. EtO\(^-\) is not so bad—alkoxide salts are stable, but they are still strong, reactive bases (we shall see below what \(pK_a\) has to do with this matter). But Cl\(^-\) is the best leaving group: Cl\(^-\) ions are perfectly stable and quite unreactive and happily carry off the negative charge from the oxygen atom. You probably eat several grams of Cl\(^-\) every day but you would be unwise to eat EtO\(^-\) or MeLi.

\(pK_{aH}\) is a useful guide to leaving group ability

It’s useful to be able to compare leaving group ability quantitatively. This is impossible to do exactly, but a good guide is \(pK_{aH}\). If we go back to the example of ester formation from acyl chloride plus alcohol, there’s a choice of Me\(^-\), EtO\(^-\), and Cl\(^-\). The leaving group with the lowest \(pK_{aH}\) is the best and so we can complete the reaction.

<table>
<thead>
<tr>
<th>Leaving group</th>
<th>(pK_{aH})</th>
</tr>
</thead>
<tbody>
<tr>
<td>Me(^-)</td>
<td>50</td>
</tr>
<tr>
<td>EtO(^-)</td>
<td>16</td>
</tr>
<tr>
<td>Cl(^-)</td>
<td>-7</td>
</tr>
</tbody>
</table>

The same is true for the reaction of acetic anhydride with an alcohol. Possible leaving groups from this tetrahedral intermediate are the following.

<table>
<thead>
<tr>
<th>Leaving group</th>
<th>(pK_{aH})</th>
</tr>
</thead>
<tbody>
<tr>
<td>Me(^-)</td>
<td>50</td>
</tr>
<tr>
<td>RO(^-)</td>
<td>16</td>
</tr>
<tr>
<td>MeCO(^2-)</td>
<td>5</td>
</tr>
</tbody>
</table>

Again the group that leaves is the one with the lowest \(pK_{aH}\).

**Leaving group ability**

The lower the \(pK_{aH}\), the better the leaving group in carbonyl substitution reactions.

Why should this be so? The ability of an anion to behave as a leaving group depends in some way on its stability—how willing it is to accept a negative charge. \(pK_a\) represents the equilibrium between an acid and its conjugate base, and is a measure of the stability of that conjugate base with respect to the acid—low \(pK_a\) means stable conjugate base, indicating a willingness to accept a negative charge. So the general trends that affect \(pK_a\), which we discussed in Chapter 8, will also affect leaving group ability. However, you must bear in mind that \(pK_a\) is a measure of stability only with respect to the protonated form of the anion. Leaving group ability is a fundamentally different comparison between the stability of the negatively charged tetrahedral intermediate and the leaving group plus resulting carbonyl compound. But it still works as a good guide. These five values are worth learning.
We can use $pK_a$ to predict what happens if we react an acyl chloride with a carboxylate salt. We expect the carboxylate salt (here, sodium formate, or sodium methanoate, $\text{HCO}_2\text{Na}$) to act as the nucleophile to form a tetrahedral intermediate, which could collapse in any one of three ways.

We can straight away rule out loss of $\text{Me}^-$ ($pK_a 50$), but we might guess that $\text{Cl}^-$ ($pK_a -7$) is a better leaving group than $\text{HCO}_2^-$ ($pK_a$ about 5), and we’d be right. Sodium formate reacts with acetyl chloride to give ‘acetic formic anhydride’.

Amines react with acyl chlorides to give amides

Using the principles we’ve outlined above, you should be able to see how these compounds can be interconverted by substitution reactions with appropriate nucleophiles. We’ve seen that acid chlorides react with carboxylic acids to give acid anhydrides, and with alcohols to give esters. They’ll also react with amines (such as ammonia) to give amides.

The mechanism is very similar to the mechanism of ester formation.

Notice the second molecule of ammonia, which removes a proton before the loss of chloride ion—the leaving group—to form the amide. Ammonium chloride is formed as a by-product in the reaction.

Here is another example, using a secondary amine, dimethylamine. Try writing down the mechanism now without looking at the one above. Again, two equivalents of dimethylamine are necessary, though the chemists who published this reaction added three for good measure.
Schotten–Baumann synthesis of an amide

As these mechanisms show, the formation of amides from acid chlorides and amines is accompanied by production of one equivalent of HCl, which needs to be neutralized by a second equivalent of amine. An alternative method for making amides is to carry out the reaction in the presence of another base, such as NaOH, which then does the job of neutralizing the HCl. The trouble is, OH⁻ also attacks acyl chlorides to give carboxylic acids. Schotten and Baumann, in the late nineteenth century, published a way round this problem by carrying out these reactions in two-phase systems of immiscible water and dichloromethane. (Carl Schotten (1853–1910) was Hofmann’s assistant in Berlin and spent most of his working life in the German patent office (There is more about Hofmann in Chapter 19.) The organic amine (not necessarily ammonia) and the acyl chloride remain in the (lower) dichloromethane layer, while the base (NaOH) remains in the (upper) aqueous layer. Dichloromethane and chloroform are two common organic solvents that are heavier (more dense) than water. The acyl chloride reacts only with the amine, but the HCl produced can dissolve in, and be neutralized by, the aqueous solution of NaOH.

Using $pK_{aH}$ to predict the outcome of substitution reactions of carboxylic acid derivatives

You saw that acid anhydrides react with alcohols to give esters: they will also react with amines to give amides. But would you expect esters to react with amines to give amides, or amides to react with alcohols to give esters? Both appear reasonable.

In fact only the top reaction works: amides can be formed from esters but esters cannot be formed from amides. Again, looking at $pK_a$ can tell us why. In both cases, the tetrahedral intermediate would be the same. The possible leaving groups are shown in the table.

<table>
<thead>
<tr>
<th>Possible leaving groups</th>
<th>$pK_{aH}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ph⁻</td>
<td>45</td>
</tr>
<tr>
<td>NH₂</td>
<td>35</td>
</tr>
<tr>
<td>MeO⁻</td>
<td>16</td>
</tr>
</tbody>
</table>

So RO⁻ leaves and the amide is formed. Here is an example. The base may be either the EtO⁻ produced in the previous step or another molecule of PhNH₂.

You will meet many more mechanisms like this, in which an unspecified base removes a proton from an intermediate. As long as you can satisfy yourself that there is a base available to perform the task, it is quite acceptable to write either of these shorthand mechanisms.
Factors other than leaving group ability can be important

In fact, the tetrahedral intermediate would simply never form from an amide and an alcohol; the amide is too bad an electrophile and the alcohol not a good enough nucleophile. We’ve looked at leaving group ability: next we’ll consider the strength of the nucleophile $Y$ and then the strength of the electrophile $RCOX$.

### Conditions for reaction

If this reaction is to go

$$
\begin{align*}
R\text{CO}_X + \overset{\text{Y}}{Y}^- & \rightarrow Y\text{CO}_X + \overset{\text{X}}{X}^-
\end{align*}
$$

1. $X$ must be a better leaving group than $Y$ (otherwise the reverse reaction would take place)
2. $Y$ must be a strong enough nucleophile to attack $RCOX$
3. $RCOX$ must be a good enough electrophile to react with $Y^-$

$pK_{aH}$ is a guide to nucleophilicity

We have seen how $pK_a$ gives us a guide to leaving group ability: it is also a good guide to how strong a nucleophile will be. These two properties are the reverse of each other: good nucleophiles are bad leaving groups. A species that likes forming new bonds to hydrogen (in other words, the $pK_a$ of its conjugate acid is high) will also like to form new bonds to carbon: it is likely to be a good nucleophile. Bases with high $pK_{aH}$ are bad leaving groups and they are, in general, good nucleophiles towards the carbonyl group. We will come back to this concept again in Chapter 17, where you will see that it does not apply to substitution at saturated carbon atoms.

### Guide to nucleophilicity

*In general, the higher the $pK_{aH}$, the better the nucleophile.*

But just a moment—we’ve overlooked an important point.

When we made acid anhydrides from acid chlorides plus carboxylate salts, we used an anionic nucleophile $RCO_2^-$ but, when we made amides from acid chlorides plus amines, we used a neutral nucleophile $NH_3$, and not $NH_2^-$. For proper comparisons, we should include in our table $ROH$ ($pK_{aH} = -5$; in other words, $-5$ is the $pK_a$ of $ROH^+$) and $NH_3$ ($pK_{aH} = 9$; in other words, 9 is the $pK_a$ of $NH_4^+$).

While amines react with acetic anhydride quite rapidly at room temperature (reaction complete in a few hours), alcohols react extremely slowly in the absence of a base. On the other hand, an alkoxide anion reacts with acetic anhydride extremely rapidly—the reactions are often complete within seconds at 0 °C. We don’t have to deprotonate an alcohol completely to increase its reactivity: just a catalytic quantity of a weak base can do this job by removing the alcohol’s proton *as it adds* to the carbonyl group. All these observations are consistent with our table and our proposition that high $pK_{aH}$ means good nucleophilicity.

### Not all carboxylic acid derivatives are equally reactive

We can list the common carboxylic acid derivatives in a ‘hierarchy’ of reactivity, with the most reactive at the top and the least reactive at the bottom. Transformations are always possible moving *down*

<table>
<thead>
<tr>
<th>Base</th>
<th>$pK_{aH}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$R^-$</td>
<td>50</td>

<td>-7</td>
</tr>
</tbody>
</table>
The hierarchy. We’ve seen that this hierarchy is partly due to how good the leaving group is (the ones at the top are best), and partly due to how good the nucleophile needed to make the derivative is (the ones at the bottom are best).

---

Delocalization and the electrophilicity of carbonyl compounds

All of these derivatives will react with water to form carboxylic acids, but at very different rates.

Hydrolysing an amide requires boiling in 10% NaOH or heating overnight in a sealed tube with concentrated HCl. Amides are the least reactive towards nucleophiles because they exhibit the greatest degree of delocalization. You met this concept in Chapter 7 and we shall return to it many times more. In an amide, the lone pair on the nitrogen atom can be stabilized by overlap with the $\pi^*$ orbital of the carbonyl group—this overlap is best when the lone pair occupies a p orbital (in an amine, it would occupy an $sp^3$ orbital).

The molecular orbital diagram shows how this interaction both lowers the energy of the bonding orbital (the delocalized nitrogen lone pair), making it neither basic nor nucleophilic, and raises the energy of the $\pi^*$ orbital, making it less ready to react with nucleophiles. Esters are similar but, because the oxygen lone pairs are lower in energy, the effect is less pronounced.

The greater the degree of delocalization, the weaker the C=O bond becomes. This is most clearly
We treat this in more detail in Chapter 15. There are two frequencies for the anhydride and the carboxylate because of symmetric and antisymmetric stretching.

evident in the stretching frequency of the carbonyl group in the IR spectra of carboxylic acid derivatives—remember that the stretching frequency depends on the force constant of the bond, itself a measure of the bond’s strength (the carboxylate anion is included because it represents the limit of the series, with complete delocalization of the negative charge over the two oxygen atoms).

\[
\begin{array}{c|c|c|c|c}

\text{R} & \text{Cl} & \text{O} & \text{O} & \text{NH}_2 \\
\hline
\nu / \text{cm}^{-1} & 1790-1815 & 1800-1850 & 1740-1790 & 1690 \\
\text{C=O} & \text{strongest} & \text{1735-1750} & \text{1610-1650} & \text{1300-1420} & \text{weakest}
\end{array}
\]

Amides react as electrophiles only with powerful nucleophiles such as HO\textsuperscript{-}. Acid chlorides, on the other hand, react with even quite weak nucleophiles: neutral ROH, for example. They are more reactive because the electron-withdrawing effect of the chlorine atom increases the electrophilicity of the carbonyl carbon atom.

**Bond strengths and reactivity**

You may think that a weaker C=O bond should be more reactive. This is not so because the partial positive charge on carbon is also lessened by delocalization and because the molecule as a whole is stabilized by the delocalization. Bond strength is not always a good guide to reactivity! For example, in acetic acid the bond strengths are surprising. The strongest bond is the O–H bond and the weakest is the C–C bond. Yet very few reactions of acetic acid involve breaking the C–C bond, and its characteristic reactivity, as an acid, involves breaking O–H, the strongest bond of them all!

The reason is that polarization of bonds and solvation of ions play an enormously important role in determining the reactivity of molecules. In Chapter 39 you will see that radicals are relatively unaffected by solvation and that their reactions follow bond strengths much more closely.

**Carboxylic acids do not undergo substitution reactions under basic conditions**

Substitution reactions of RCO\textsubscript{2}H require a leaving group OH\textsuperscript{-}, with \(pK_a = 15\), so we should be able to slot RCO\textsubscript{2}H into the ‘hierarchy’ on p. 000 just above the esters RCO\textsubscript{2}R\textprime. However, if we try to react carboxylic acids with alcohols in the presence of a base (as we would to make esters from acyl chlorides), the only thing that happens is deprotonation of the acid to give the carboxylate anion. Similarly, carboxylic acids react with amines to give not amides but ammonium carboxylate salts, because the amines themselves are basic.

Once the carboxylic acid is deprotonated, substitutions are prevented because (almost) no nucleophile will attack the carboxylate anion. Under neutral conditions, alcohols are just not reactive enough to add to the carboxylic acid but, with acid catalysis, esters can be formed from alcohols and carboxylic acids.

**Acid catalysts increase the reactivity of a carbonyl group**

We saw in Chapter 6 that the lone pairs of a carbonyl group may be protonated by acid. Only strong acids are powerful enough to protonate carbonyl groups: the \(pK_a\) of protonated acetone is \(\approx 7\), so, for example, even 1M HCl (pH 0) would protonate only 1 in \(10^7\) molecules of acetone. However, even proportions as low as this are sufficient to increase the rate of substitution reactions at carbonyl groups enormously, because those carbonyl groups that are protonated become extremely powerful electrophiles.
It is for this reason that alcohols will react with carboxylic acids under acid catalysis. The acid (usually HCl, or H₂SO₄) reversibly protonates a small percentage of the carboxylic acid molecules, and the protonated carboxylic acids are extremely susceptible to attack by even a weak nucleophile such as an alcohol.

Acid catalysts can make bad leaving groups into good ones
